**DIURNA** (Latreille). A section of lepidopterous insects, corresponding with the Linnæan genus *Papilio*, or butterflies, being distinguished by having the margin of lower wings not furnished at the base with a scaly bristle for retaining the upper wings in their proper situations, these, as well as the second pair, being generally perpendicularly elevated during repose; the antennæ are generally terminated by a club, and the larvæ have sixteen legs. The perfect insect, always furnished with a spiral tongue, flies by day, and the under surface of the wings is not less beautifully variegated than the upper. Having, under the article **BUTTERFLY**, entered at length into the natural history of these beautiful insects, we shall here simply give a slight sketch of their distribution into groups, established upon their diversities of structure.

Fam. 1.—*Papilionidæ*. Anterior legs not abbreviated, fit for walking, alike in both sexes. Pupa angulated, suspended, and braced across the middle. Antennæ not hooked at the tip. Here belong the genera *Papilio*, *Zelima*, *Parnassius*, *Thais*, *Pieris*, *Pontia*, *Colas*.

Fam. 2.—*Nymphalidæ*. Anterior legs abbreviated, not fitted for walking; ungues bifid; pupa angulated, and merely suspended by the tail; middle cell of the lower wings closed. Genera: *Cethosia*, *Argynnis*, *Melitæa*, *Vanessa*, *Libythea*, *Biblis*, *Nymphalis*, &c.

Fam. 3.—*Heliconiæ*. Pupa smooth, suspended only by the tail; anterior legs imperfect; discoidal cell sometimes open. *Danaïs*, *Heliconia*, *Acræa*, &c.

Fam. 4.—*Lycænidæ*. Anterior legs semi-abbreviated; claws minute; pupa smooth, braced, larva onisciform. Genera. *Polyommatus*, *Thecla*, &c.

Fam. 5.—*Hesperidæ*. Anterior legs not abbreviated; antennæ hooked at the tips; pupa smooth, braced, and foliculated. Genera: *Hesperia*, *Thymele*, &c.

These characters, it will be seen, are in some degree

derived from the preparatory stages of the insects; indeed, these considerations afford much more important clues to the classification of insects than they were imagined to possess by the earlier authors upon this branch of natural history. Of those who adopted a contrary opinion, Schrank may especially be noticed. He consulted metamorphosis in its various modifications, in his arrangement, and on its importance as a guide to minor sub-divisions, he has the following ingenious observations, quoted by Dr. Horsfield in his *Lepidoptera Javanica*:—"Metamorphosis, in its larva state, may, and I think must be taken into the characters of the genus, in the absence of other sufficiently distinctive notices. Those botanists who have derived their systems primarily from the fruit, have nevertheless a regard for the flower, and by this means reciprocally elucidate existing obscurities. Caterpillars are the flowers of the lepidoptera. They are, indeed, not always present when the perfect insects are before the examiner. But is the case different with the botanist?" And Mr. MacLeay says to the same effect: "As the knowledge of the whole life of an insect must make us better acquainted with its nature than a mere description of one of its forms, in the same proportion ought metamorphosis to outweigh every other principle of arrangement."

**DIVER**—*Colymbus*. A genus of web-footed birds, and one of the most aquatic of the whole order. They appear in structure and in habits as literally made for the water, and the water only; and they have equal command of themselves on and under the surface of that element. They are chiefly natives of the northern hemisphere, and of the more northerly seas, being birds peculiarly fitted for contending with the storm in the water itself, and probably getting to a greater depth than that to which the water is disturbed by the waves. They are especially abundant about projecting headlands in the northern countries, where the current runs strong, and the surf and spray occasionally beat with great violence. But amid the turmoil of the storm, the divers appear as much at home in the foaming water as the small birds do in the groves on the gentlest morning of May. In such situations they may be seen driving about, now appearing in the trough of the waves, now boring through the ridges, now on the wing for a little space, but anon plunging into the water. At such times and in such places the fry of fishes, which remain and feed much nearer the surface than such as are full grown, are collected in abundance, and many of them lose command of themselves in the troubled waters, so that they are brought helpless to the line on its slope upon which the wave turns; for it is to be understood that waves do not roll onward in rapid progressive motion as they have the appearance of doing to a spectator, they merely swing in times proportionate to their lengths, that is to half the distance between the bottom of the trough and the top of the ridge, as measured on the slope; and as the turning point, or rather line, taken in the length of the wave, is the place of no upward or downward motion, it is there where the small fishes and other surface animals are accumulated while the storm lasts; and it is to profit by those accumulations that the divers are found driving through the waves on such occasions.

Cuvier makes the divers a family consisting of three genera, the divers properly so called, the grebes, and the guillemots; but as the word diver is in this country restricted to the genus *Colymbus*, and as the

guillemots have some differences of habit, we shall restrict this article to the divers properly so called.

Their characters are: the bill of moderate dimensions; straight, compressed, and very sharp at the point; the nostrils at the base, lateral, oblong, and half closed by a membrane; the legs placed far behind, with the tarsi compressed or flattened sideways; three front toes very long, and webbed to their points, and the hind toes short and united to the inner toe by a rudimental web. The legs are articulated very far backwards and wide of each other, so that though they act powerfully in the water they are very ill adapted for walking on land; and when the birds attempt this, they are obliged to carry their bodies in nearly a vertical position, and roll them along with their steps, which are both short and awkward. The wings are short, but remarkably close in their feathering; and the tail is also very short and rounded. The form of the body is long and flat, the breadth being greater than the depth; and the head and neck are comparatively slender, the former gradually fining off into the strong and sharp bill, which answers equally for seizing the prey or transfixing it by a thrust. The plumage over their whole bodies is remarkably close and compact, and how long soever they remain in the water they are never wetted. They spend the greater part of their time in the water unless when they have nests; and as they are very energetic in their motions, they are very voracious in their eating. They are also very miscellaneous feeders, capturing fish, small marine animals, and not refusing vegetable food if it comes in their way. Their summer quarters are chiefly in the north, where they form their nests upon small islands, or projecting headlands where they are subject to be but little disturbed. Their eggs are usually only two in number, and as is the case with the greater number of sea birds they make no formal nest. It is a fact worth attending to, as showing the difference between depending on the land and depending on the sea, that the eggs of land birds are, generally speaking, much more numerous than those of sea birds, while the sea birds themselves are much more numerous than land birds. Sea birds indeed, though they have at all times considerable labour in the finding of their food, have yet plenty of it at most seasons; and besides, they are exempted from many of the casualties which land birds have to suffer; and not the least of these are the attacks of beasts and birds of prey. From both of these the sea birds are comparatively free, and perhaps they owe some part of their safety to the unpalatableness of their flesh; for many of them are so rank that it is doubtful whether even a starved raven, the least dainty perhaps of animals, would condescend to make a meal of some of them; and as for the sea eagles and ospreys, they are more partial to a fish dinner.

In the divers, the sexes do not differ greatly in appearance; but the young differ so much from the old birds that they have been formed into separate species; and not only this, but as the young require three years before they assume the proper plumage of maturity, and as they continue growing all this time, one species has sometimes been multiplied into four, by giving separate specific accounts of birds of one year, birds of two years, birds of three years, and birds in their plumage of maturity. We shall notice one or two of the leading species.

THE GREAT NORTHERN DIVER—*C. glacialis*. This

is a very large species, and one which attracts a good deal of attention. Its bill is upwards of four inches in length, with a strong ridge or keel above the nostrils, and with the under mandible deepest in the middle, a form which gives much stiffness and power to that part of the organ. The size is subject to considerable variation; but the largest are from two feet and a half to three feet in the length of the body, and from four feet and a half to five feet in the stretch of the wings; and when they are of this size, and fat, they weigh from twelve to fifteen pounds. The head and neck are black, but the neck is surrounded by two white collars freckled with black, the upper part is black powdered with white spots, and the under part white. In winter those birds frequent the northern parts of both continents; but they breed in the marshes, or the fresh water pools, and not on the rocks. We believe few of them nestle on the main land, even in the northernmost part of Scotland; but they are by no means rare in the western islands and the Orkneys, and they are met with in Norway, Sweden, and the north of Europe generally, and also in Iceland and Greenland, and in fact in all the countries joining the Arctic Seas. In their breeding places they love retirement, and their nests are usually concealed among reeds or other tall aquatic herbage. Their eggs bear some resemblance to those of the goose, only they are very slightly spotted with black.

The Great Northern Diver.

To capture the eggs of the great diver, or the young birds, if the mother is near, is a matter of some hazard, just as the finding of the nest and getting at it are matters of some difficulty. It should seem that, in placing the nest, inaccessible ground, as well as concealment, were the object of these birds; for they are generally in places where they can neither be reached in boats nor on foot; and if they are reached, and the old bird is near, she makes a very determined, and at the same time, a very formidable resistance. Her bill

is darted out with nearly as much rapidity as that of a bittern, and as the bird is heavier, the bill thrusts like a bayonet, so that both bird and nest are tolerably well secured from the predatory quadrupeds of those places. In the summer season these birds subsist almost entirely on the smaller species of surface fishes, or the young of the larger ones; and, notwithstanding their size and weight, in the capture of their prey their adroitness is very great. They have equal address in avoiding danger, which renders it very difficult to shoot them on the water; for as they dive, the shot glances, and they are safe. Sometimes, however, they are taken, or rather take themselves, on the baited hooks of the fishermen's lines, and at other times they get entangled in nets at greater depths below the surface than one would be apt to suppose.

In winter they migrate southwards, and on their migratory journeys they are capable of lofty and rapid flight. The young are the most prone to take these excursions; and as they make their way to the inland lakes of France and Germany, and sometimes even as far as Switzerland. The descriptions of these young ones have led to some of the confusion which there is about the species. They are not rare upon some places of the north coast of Scotland in the winter season, but they seldom make their appearance on the English shores unless the winter is very severe.

These birds, and indeed all the diving birds of the Polar seas, are remarkably well defended against the cold to which they are exposed in their dives. Their skins are remarkably strong and tough; and the down upon them among the roots of the feathers is very close. They have also a pretty thick layer of fat all over the body, immediately under the skin. Their skins are so strong, and the down upon them adheres so firmly, that the people of the northern islands dress and tan them, and make of them very warm and durable articles of clothing.

The voice of these birds is strong, harsh, and peculiar, and resembles more the barking of a dog than the sound uttered by almost any other of the feathered creation. They are in short altogether very extraordinary birds.

**RED-THROATED DIVER**—*Colymbus septentrionalis*. This is a much smaller species than the former, but it is more elegantly made. The length does not exceed two feet, or the weight much more than three pounds. The bill is about three inches long, slender and pointed, of a black colour, and slightly curved upwards. The crown of the head and back of the neck are purplish black with raised white margins to the feathers. The sides of the neck and head and cheeks are dark grey; the upper part is very dark olive with the margins of the feathers paler, and the coverts of the wings dusky with white spots. The front of the neck is brownish-red, from which the name of red-throated diver is derived; the rest of the under part is silvery white with a black bar on the vent. The young differ considerably, not only from the old, but in the different stages in their own growth. At first they are all over dusky on the upper part and dull white on the under; and next the grey on the head appears, and the back is spotted. The third change which they undergo is the acquiring of the mature plumage, and the reddish brown on the throat.

In some parts of the country, Orkney, we believe, this species is called the rain-goose; because when it screams, or rather croaks, the people of that country say that it predicts rain. It is probable, however, that

there is not very much truth in this prophecy; and yet many birds, both of the land and the sea, are apt to be clamorous before foul weather.

Like the former species, this one breeds in the marshes. It is more abundant in the more northerly of the Scottish islands, and more discursive to the British bays and estuaries in the winter, being found in the Thames, though not very frequently. The eggs of this species are very much elongated, of an olive brown colour, and marked with a few dusky spots. The nest is made with some care of moss and grass, and the female lines it with down from her own breast.

Red-throated Diver.

**THE BLACK-THROATED DIVER**—*Colymbus arcticus*. This one is a little larger than the former, being about three inches longer, four inches more in the stretch of the wings, and nearly a pound heavier. The front, the throat, the fore neck, and the back and rump are black; the sides of the neck mottled black and white; the sides of the back and scapules black with white spots. The habits agree pretty nearly with those of the others, the nests being also on the margins of lakes; the eggs are also two in number; but unlike those of the last species, they are white. The young are dusky above and white below at the first; the head next becomes grey, and the sides of the head spotted with black; and the last stage of the plumage is the appearance of the black on the fore neck, and the black and white mottlings on the sides of the back and the scapulars.

**DIVING WATER SPIDER** (*ARGYRONETA*, Latreille), a genus of pulmonary arachnida, belonging to the family *Araneida*, but forming, according to Walckenaer, a distinct family named *Nayaides*. The four central eyes form a quadrangle, the two lateral ones on each side touching each other, and placed upon a slight eminence; the first and fourth pairs of legs are the longest. The type species *Aranea aquatica* (Linnaeus), is very common, and of a brownish black colour, with the abdomen silky, and with four impressed spots on the back. It resides in slow running waters and ditches, in which it swims about with a bubble of air attached to its abdomen, and spinning a most beautifully constructed web of white silk, in the form of half the shell of a pigeon's egg, or like a diving bell, with the mouth downwards, as its retreat, at the bottom of the water, and which is attached by numerous threads to the surrounding plants. In this it devours its prey, and deposits its bundle of eggs, which

it watches with great care. In this also it passes the winter, having first closed the mouth. The males as well as the females construct these cells.

**DOCK.** The vulgar name of a British weed called by botanists *Rumex*. Including the different sorts of sorrel, there are nine or ten species of *Rumex* in Britain; the large leaved are called docks, and the small leaved are called sorrels.

**DODO**—*Didus*. A genus of birds inhabiting, or rather said to have inhabited, the island of Madagascar, but which is now extinct, and indeed the existence of it at any time, as answering to the descriptions which are given by the older writers, is somewhat doubtful. The first description, or rather the only one which even pretends to be founded on actual observation, was given by the Dutch, when they first visited that part of the world; and of which an oil painting was made about the same period. The description and a copy of the painting were given by Cluseus in his account of exotic birds; the picture was also copied by Edwards; and from these sources the bird got into the popular books as a living inhabitant of the earth. But the remains of it are very scanty, and it is doubtful whether they have all belonged to the same kind of bird; there is a foot in the British Museum, the mutilated remains of a head in the Ashmolean Museum of Oxford, and a skull, a sternum, and some bones of the extremities were sent to Paris, which last were discovered in a cave in the small island of Rodriguez, about a thousand miles to the eastward of Madagascar, about fifty years ago. The foot is webbed, and very like the foot of a penguin; and if there ever was such a bird as the dodo, it must have been, like the patagonian penguin, nearly incapable of flight. The account given in the books is, that at the time when the Dutch first visited this Archipelago, that is, Madagascar and the small isles to the eastward, these birds were found in abundance; but the result of all subsequent inquiry has been nothing more than the fragments which we have mentioned. There have been two species of this bird mentioned; but one of them, *Didus solitarius*, and indeed another, *Didus Nazarenus*, are certainly spurious, and as no more of the third can be found, it scarcely belongs to popular natural history.

*Didus ineptus.*

This species (*Didus ineptus*), of which we give a figure, without vouching for its being a likeness of

any bird that ever lived, is described as being one of the largest of the feathered race, but the most uncouth and unwieldy of the whole. Its colour is said to have been black, with only a thin covering of feathers, and the head covered with a membranous hood. Only four or five short black feathers in the place of wings, and a tuft of curly feathers instead of tail. The tarsi short, very thick and stout, and covered with brown scales; the toes very short, webbed, and without any claws. The bill very large, yellow at the base, black at the tip, and blue in the middle portion of its length.

The recent discovery of the apteryx (see the article **APTERYX**) on the island of New Zealand, and the fact that only the one specimen of that curious bird had been seen by Europeans, gave some ground for believing that there might possibly be in the southern hemisphere, which is remarkable for the singularity of many of its animals, some such bird as this same dodo; but the form given to the bird in the picture, and the weight ascribed to it, namely more than fifty pounds, are rather contradictory of any hope of seeing it. The organisation of the apteryx is no doubt peculiar; as the bird can neither fly nor swim, and from the shortness of its legs cannot be a very swift walker; but the apteryx has still an organisation which one can understand, and perceive that it is not badly adapted for the situations in which it is said to be found, the rocky and stony places on the east side of New Zealand. The dodo, as described, has on the other hand no distinct system of locomotion, and is quite a bird of the *ultima thule*, fit for neither land, sea, nor air. The feet are webbed, but there is nothing to answer to them in swimming; the absence of wings forbids the notion of an air bird, and the feet are not adapted for walking.

**DOG**—*Canis*. A genus of carnivorous mammalia, and one of the most interesting of the whole class. It consists of several genera, or rather perhaps subgenera; the dog properly so called, the wolf, the fox, the jackall, and the hyæna, all of which produce hybrids, and generally speaking, we believe fertile hybrids with each other; but though this warrants the consideration and description of all these animals as one group, and though they have many characters in common, yet they are so numerous, and the peculiarities of each are so distinct, that we shall perhaps best observe clearness of description, and propriety of arrangement, if we treat of them under their common names of **DOGS**, **FOXES**, **HYÆNAS**, **JACKALLS**, and **WOLVES**. These five divisions fall into two classes, which are founded upon their principal habits. The dogs and wolves have the pupil of the eye round, and they are social in their predatory huntings; and though these huntings are not confined to the day, yet they are, generally speaking, more of diurnal than of nocturnal animals. The foxes and hyænas, on the other hand, are less social in their characters, the foxes especially are of solitary habits, and they are more nocturnal than otherwise, though the time at which they seek their prey is early morning rather than during the darkness of the night. The whole of the group however consists of animals which are peculiarly flexible in their characters; and, the human race excepted, perhaps yield more to climatal and local circumstances than any other family of carnivorous mammalia. They are found in all climates, and they appear to have wonderful facilities of adapting themselves to the climate, being almost destitute of hair in the very warm latitudes, but becoming

clothed with remarkably thick fur when carried to cold climates. This change, not in the same species merely, but in the same individual animal, is so remarkable that some of the dogs which were carried out by our voyagers and travellers to the polar regions of North America, and wintered in the extreme cold there, acquired a fur of so remarkable a thickness that while they crouched by the winter fires their fur was burnt in holes half way down to the skin without their being at all sensible of the heat.

The character of the genus are, that they are digitigrade in their walking, or walk upon their toes, the claws of which are not retractile, or used in any way as prehensile instruments in the capture of their prey, which in these animals is uniformly captured by speed, and following either by sight or on the scent, the strength of the prey determining whether it shall be hunted singly or by a combined pack. The teeth are, six incisors in each jaw, and one strong canine in each side of each, with six teeth above in each jaw, and seven in each below. The first three behind the canines in the upper jaw, and the first four in the lower, have trenchant or cutting edges, adapted for bruising flesh; the great carnivorous teeth which follow these have two points in the upper jaw, with a small tubercle on the inner side. The two last teeth in each side of both jaws are also tuberculated at their summits. In those varieties which are found in a state of nature the muzzle is generally elongated, and the gape wide, the effect of the jaws in killing the prey being that of a snap, in which the rapid motion of the jaw gives effect to the weight; and these species or varieties (for it is exceedingly difficult in this species of animals to say what is a species and what a variety) the ears are generally erect; but in the domesticated ones the varieties are so numerous that it is hardly possible to give any description of them.

No specific form or character of covering can be taken as generally characteristic of dogs; for though their characters are always expressive of the family, as distinguished from every other race of animals, they differ so much from each other, in size, in shape, in the character of their covering, and are so in their propensities, that they have absolutely nothing of external character which will apply to the whole race. The length of their jaws and muzzle, and the shapes of their ears, are exceedingly variable; but the tongue is always smooth, and instead of lacerating, like that of the cat family, its application to wounded or diseased parts has rather a healing tendency; they have five toes on the fore-feet, and generally four on the hind ones, though in some of the varieties there is a partial development of the fifth one. The females go sixty-three days, and the litter consists usually of three, four, or five, though sometimes of as many as ten or a dozen; the puppies are always produced with the eyes closed, and do not open them for ten or twelve days after. They live on the average about fourteen or fifteen years, but there are great differences arising from climate, breed, and other circumstances.

If we take the domesticated races, and it is doubtful whether there are any dogs which have not been partially domesticated, though some have unquestionably degenerated, there are no animals which show so much attachment to man; and the anecdotes which are recorded of the fidelity of dogs would fill many volumes. Perhaps justice is not more effectually done to their characters in a general, and we may say unphilosophical view, than in the following passage

which we quote from Mr. Burchell's *Travels in Africa*: "Our pack of dogs," says Mr. Burchell, "consisted of about five and twenty of various sorts and sizes. This variety, though not altogether intentional, as I was obliged to take any that could be procured, was of the greatest service in such an expedition, as I observed that some gave notice of danger in one way, and others in another. Some were more disposed to watch against men, and others against wild beasts; some discovered an enemy by their quickness of hearing, others by that of scent; some for speed in pursuing game; some were useful only for their vigilance and barking; and others for their courage in holding ferocious animals at bay. So large a pack was not indeed maintained without adding greatly to our care and trouble, in supplying them with meat and water, for it was sometimes difficult to procure for them enough of the latter; but their services were invaluable, often contributing to our safety, and always to our ease, by their constant vigilance, as we felt a confidence that no danger could approach us at night without being announced by their barking. No circumstances could render the value and fidelity of these animals so conspicuous and sensible as a journey through regions which, abounding in wild beasts of almost every class, gave continual opportunities of witnessing the strong contrast in their habits, between the ferocious beasts of prey, which fly at the approach of man, and these kind but too often injured companions of the human race. Many times, when we have been travelling over plains where those have fled the moment we appeared in sight, have I turned my eyes towards my dogs to admire their attachment, and have felt a grateful affection toward them for preferring our society to the liberty of other quadrupeds. Often, in the middle of the night, when all my people have been fast asleep around the fire, have I stood to contemplate these faithful animals lying by their side, and have learnt to esteem them for their social esteem to mankind. When wandering over pathless deserts, oppressed with vexation and distress at the conduct of my own men, I have turned to these as my only friends, and felt how much inferior to them was man when actuated only by selfish views.

"The familiarity which subsists between this animal and our own race is so common to almost every country of the globe, that any remark upon it must seem superfluous; but I cannot avoid believing that it is the universality of the fact which prevents the greater part of mankind from reflecting duly on the subject. While almost every other quadruped fears man as its most formidable enemy, here is one which regards him as his companion, and follows him as his friend. We must not mistake the nature of the case: it is not because we train him to our use, and have made choice of him in preference to other animals, but because this particular species feels a natural desire to be useful to man, and from spontaneous impulse attaches itself to him. Were it not so, we should see in various countries an equal familiarity with various other quadrupeds, according to the habits, the taste, or the caprice of different nations. But everywhere it is the dog only takes delight in associating with us, in sharing our abode, and is even jealous that our attention should be bestowed on him alone; it is he who knows us personally, watches for us, and warns us of danger. It is impossible for the naturalist, when taking a survey of the whole animal creation, not to feel a conviction that this friendship between two creatures so different from each other

must be the result of the laws of nature ; nor can the humane and feeling mind avoid the belief that kindness to those animals from which he derives continued and essential assistance is part of his moral duty."

The breeds of the dog, in a state of partial or complete domestication, are so numerous however, and the propensities of different breeds, and of different individuals of the same breed, are so varied, that there is no possibility of giving any thing like a general character of the race, while even a judicious selection of the tales of their biography would fill many volumes. It is impossible not to admire the sagacity and the strength of attachment which many animals of this genus evince ; and as they appear, when properly domesticated, to merge all their own attachments and interests in devotedness to the cause of their masters, it is exceedingly difficult to account for their conduct upon any of the known principles of animal physiology.

That there is nothing at all approaching to what we call reason, or a process of judgment, as men judge of cause and effect, in the sagacity of dogs, is certain, because instances are recorded of the effects of their sagacity, which totally surpass all reason, and absolutely appear as if they were the results of some occult principle, to the nature of which we have no clue. The power of sensation in these animals, especially of the sense of smell in such of them as in a state of nature make use chiefly of that sense, in obtaining their prey, is perfectly wonderful ; and they appear to know not only the spot or scent left by an animal, where there is no impression upon the ground in the least cognisable by human senses ; but they appear to recognise a difference of scent, not only in different animals of the same species, but absolutely in different inanimate substances ; and what is more wonderful, they appear to know the direction in which that which they pursue or follow, has proceeded, even when it has long gone by. We have well authenticated instances of dogs having been carried within carriages, over long distances, where they had no means of examining a bit of the road ; and yet of their returning when liberated, with the most unerring certainty, to the places from which they were originally carried in this artificial manner. A dog too who has had any experience in following on the scent, will not continue for any length of time on the back scent, or direction opposite to that in which the chase is gone, but after a trial or two with his nose, will double round and follow the forward scent or direction which the animal has taken. This is, perhaps, the most extraordinary case of animal sensation with which we are acquainted, and it shows how admirably nature can adapt the qualities of animals to the necessities of their modes of life ; and also how economical nature is in the distribution of even these wonderful endowments. Dogs which find their prey by the sight never have this wonderful acuteness of smell ; and those which have this in perfection have not the powerful sight of those which are without it, neither are they, generally speaking, so swift-footed. But those which have the sense of smell most powerful are, generally speaking, more persevering and staunch than the others, and can follow their game over longer distances, and also find it again much more readily in the case of losing it.

Dogs are, generally speaking, social to some extent or other, even in those conditions which we may consider as more nearly approaching to a state of rude nature ; and, in the formation of their social unions,

for the accomplishment of particular purposes, their instincts are not less wonderful than in the acuteness of their sense of smelling. We shall mention one instance of this, the authenticity of which may, we believe, be relied on ; though it is not easy to account for it upon any known principle either of instinct or of reason, or of that imaginary principle which they who seek to explain that in animals which is not explainable, are in the habit of gratuitously endowing them with. All attempts at explanation of this kind are unwise in principle and ineffective in practice ; and, therefore, attempting them does not admit of any defence on the score of sound judgment. In all parts of nature, in the vegetable and the mineral kingdoms as well as the animal, and even in the simplest substances, or at all events the most apparently simple substances which we meet with in those kingdoms, there are puzzles every bit as inexplicable as the keen senses and wonderful sagacity of the dog ; and we need not vex ourselves at being unable to explain the rationale of these upon any principles analogous to those of which we understand the working, until we have explained why every plant and every animal is, within certain limits, true to its specific type ; and why every crystallisable mineral is faithful to the primary form of its crystal. Throughout the whole of nature, we know very little of the "whys" and "wherefores," and perhaps we should best consult our wisdom and our dignity if we made no attempts to waste our time in speculations in those departments of nature respecting which we must remain for ever ignorant. But to proceed to our anecdote, of which no explanation can, we believe, be given :—

A gentleman residing in the county of Fife, and not very far from the city of St. Andrews, was in possession of a very fine Newfoundland dog, which was remarkable alike for its tractability and its trustworthiness. At two other points, each distant about a mile from each other, and at the same distance from this gentleman's mansion, there were two other dogs, of great power, but of less tractable breeds, than the Newfoundland one. One of these was a large mastiff, kept as a watch-dog by a farmer, and the other a staunch bull-dog that kept guard over the parish mill. As each of these three was lord-ascendant of all animals at his master's residence, they all had a good deal of aristocratic pride and pugnacity, so that two of them seldom met without attempting to settle their respective dignities by a wager of battle.

The Newfoundland dog was of some service in the domestic arrangements, besides his guardianship of the house ; for every forenoon he was sent to the baker's shop in the village, about half a mile distant, with a towel containing money in the corner, and he returned with the value of the money in bread. There were many useless and not over civil curs in the village, as there are in too many villages throughout the country ; but in ordinary the haughty Newfoundland treated this ignoble race in that contemptuous style in which great dogs are wont to treat little ones.—When the dog returned from the baker's shop he used to be regularly served with his dinner, and went peaceably on house duty for the rest of the day.

One day, however, he returned with his coat dirtied and his ears scratched, having been subjected to a combined attack of the curs, while he had charge of his towel and bread, and so could not defend himself. Instead of waiting for his dinner as usual, he laid down his charge somewhat sulkily, and marched off ;

and, upon looking after him, it was observed that he was crossing the intervening hollow in a straight line for the house of the farmer, or rather on an embassy to the farmer's mastiff. The farmer's people noticed this unusual visit, and they were induced to notice it from its being a meeting of peace between those who had habitually been belligerents. After some intercourse of which no interpretation could be given, the two set off together in the direction of the mill; and, having arrived there, they in brief space engaged the miller's bull-dog as an ally.

The straight road to the village where the indignity had been offered to the Newfoundland dog passed immediately in front of that dog's master's house, but there was a more private and more circuitous road by the back of the mill. The three took this road, reached the village, scoured it in great wrath, putting to the tooth every cur they could get sight of; and having taken their revenge, and washed themselves in a ditch, they returned, each dog to the abode of his master; and, when any two of them happened to meet afterwards, they displayed the same pugnacity as they had done previous to this joint expedition.

It should seem that in this case there was a mere momentary concert for the accomplishment of one object among three dogs differing considerably in their habits, and that when this momentary purpose was accomplished, the wonted animosity of the three returned, and they fought as readily with each other as ever. But it does not appear that all casual, or apparently casual interferences of dogs for the benefit of each other, pass off in this momentary way; for there is another well authenticated anecdote of two dogs at Donaghadee, in which the instinctive daring of the one by the other caused a friendship, and as it should seem a kind of lamentation for the dead, after one of them had paid the debt of nature. This happened while the government harbour or pier for the packets at Donaghadee was in the course of building, and it happened in the sight of several witnesses.—The one dog in this case also was a Newfoundland, and the other was a mastiff. They were both powerful dogs; and, though each was good natured when alone, they were very much in the habit of fighting when they met. One day they had a fierce and prolonged battle on the pier, from the point of which they both fell into the sea; and, as the pier was long and steep, they had no means of escape but by swimming a considerable distance. Throwing water upon fighting dogs is an approved means of putting an end to their hostilities: and it is natural to suppose that two combatants of the same species tumbling themselves into the sea would have the same effect. It had, and each began to make for the land as he best could. The Newfoundland being an excellent swimmer very speedily gained the pier, on which he stood shaking himself; but at the same time watching the motions of his former antagonist, which, no swimmer, was struggling exhausted in the water, and just about to sink. In dashed the Newfoundland dog, took the other gently by the collar, kept his head above water, and brought him safely on shore. There was a peculiar kind of recognition between the two animals; they never fought again, they were always together; and when the Newfoundland dog had been accidentally killed by the passage of a stone waggon on the railway over him, the other languished and evidently lamented for a long time.

We must not wonder at this permanent attachment,

apparent gratitude, and apparent memory of grief, because there are very many instances of dogs who have not only refused to quit the bodies of their human masters, but have laid themselves down on their graves, refusing all consolation and all nourishment, and actually continued there till they perished of hunger. Now, if we find instances in which dogs have done this for human masters, or more strictly speaking human companions, we can hardly question its existence as between one dog and another, if the proper circumstances shall call it into exercise. The companionship which the dog feels for man is still part of the character of the animal as a dog, and, therefore, though we do not so well understand the manner in which it is brought about, we have every reason to believe that it must be stronger as between dog and dog, than as between a dog and any other animal. But the communications of animals with each other, and the means which social ones have of forming those connexions with each other which may be called simple attachments, as not being connected either with their feeding or with their physiology, are matters very difficult to be explained.

Perhaps no description of the general character of any animal is more accurate than that of the dog by Buffon; and therefore we shall prefer giving a portion of it in substance to any thing which we could originally write; and we do this the more readily, that popular description is almost all that can be written, except as referring to particular species. The dog, independently of the beauty of his form, his vivacity, force, and swiftness, is possessed of all those internal qualifications that can conciliate the affections of man, and make the tyrant a protector. A natural share of courage, an angry and ferocious disposition, renders the dog in its savage state a formidable enemy to all other animals: but these very readily give way to very different qualities in the domestic dog, whose only ambition seems the desire to please: he is seen to come crouching along, to lay his force, his courage, and all his useful talents at the feet of his master; he waits his orders, to which he pays implicit obedience; he consults his looks, and a single glance is sufficient to put him in motion; he is more faithful even than the most boasted among men; he is constant in his affections, friendly without interest, and grateful for the slightest favours; much more mindful of benefits received, than injuries offered, he is not driven off by unkindness; he still continues humble, submissive, and imploring; his only hope to be serviceable, his only terror to displease; he licks the hand that has been just lifted to strike him, and at last disarms resentment by submissive perseverance.

More docile than man, more obedient than any other animal, he is not only instructed in a short time, but he also conforms to the dispositions and the manners of those who command him. He takes his tone from the house he inhabits; like the rest of the domestics, he is disdainful among the great, and churlish among clowns. Always assiduous in serving his master, and only a friend to his friends, he is indifferent to all the rest, and declares himself openly against such as seem dependent like himself. He knows a beggar by his clothes, by his voice, or his gestures, and forbids his approach. When at night the guard of the house is committed to his care, he seems proud of the charge; he continues a watchful sentinel, he goes his rounds, scents strangers at a dis-

tance, and gives them warning of his being on duty. If they attempt to break in upon his territories, he becomes more fierce, flies at them, threatens, fights, and either conquers alone, or alarms them who have most interest in coming to his assistance; however, when he has conquered, he quietly reposes upon the spoil, and abstains from what he has deterred others from abusing; giving thus at once a lesson of courage, temperance, and fidelity.

From hence we see of what importance this animal is to us in a state of nature. Supposing, for a moment, that the species had not existed, how could man, without the assistance of the dog, have been able to conquer, tame, and reduce to servitude every other animal? How could he discover, trace, and destroy those that were noxious to him? In order to be secure and become master of all animated nature, it was necessary for him to begin by making a friend of part of them; to attach such of them to himself, by kindness and caresses, as seemed fittest for obedience and active pursuit. Thus the first art employed by man was, in conciliating the favour of the dog; and the fruits of this art were, the conquest and peaceable possession of the earth.

The generality of animals have greater agility, greater swiftness, and more formidable arms, from nature, than man; their senses, and particularly that of smelling, are far more perfect: the having gained, therefore, a new assistant, particularly one whose scent is so exquisite as that of the dog, was the gaining a new sense, a new faculty, which before was wanting. The machines and instruments which we have imagined for perfecting the rest of the senses, do not approach to that already prepared by nature, by which we are enabled to find out every animal, though unseen, and thus destroy the noxious, and use the serviceable.

The dog, thus useful in himself, taken into a participation of empire, exerts a degree of superiority over all animals that require human protection. The flock and the herd obey his voice more readily even than that of the shepherd or the herdsman; he conducts them, guards them, keeps them from capriciously seeking danger, and their enemies he considers as his own. Nor is he less useful in the pursuit; when the sound of the horn, or the voice of the huntsman, calls him to the field, he testifies his pleasure by every little art, and pursues with perseverance those animals which, when taken, he must not expect to divide. The desire of hunting is, indeed, natural to him, as well as to his master, since war and the chase are the only employ of savages. All animals that live upon flesh hunt by nature; the lion and the tiger, whose force is so great that they are sure to conquer, hunt alone and without art; the wolf, the fox, and the wild dog, hunt in packs, assist each other, and partake the spoil. But when education has perfected this talent in the domestic dog, when he has been taught by man to repress his ardour, to measure his motions, and not to exhaust his force by too sudden an exertion of it, he then hunts with method, and always with success.

Both the origin and the progressive history of the dog, are matters which defy all investigation; neither can it be said whether all the varieties now existing are or are not from one original stock. Or even whether the wolf be not a closely allied species, and perhaps identically the same. It is useless, however, to enter upon any investigation upon this question;

for the data are too few for warranting a conclusion either one way or another. Dogs appear to be the most obedient of all animals, both to natural circumstances and to artificial treatment; and so there is no knowing how far the differences which are observed among them are owing to the one of those causes or to the other. Of those dogs which are left as it were in a state of nature, or which are not bred or trained in any particular way, there are even greater differences than there are among those which are trained and kept with care. So much is this the case, that those who are in the habit of travelling much in the wilder parts of the country, know the different districts as well from the appearance of the dogs as from any thing else.

Dogs even appear to learn from the general manners of those with whom they associate, as may be observed even in common society. Dogs kept by the vicious, whether they are kept for fighting, poaching, or other ruffian practices, or not, are invariably vicious dogs; and, on the other hand, dogs which live with persons of mild manners and regular habits, when not chained up, which is a species of slavery to which dogs are very adverse, are always mild.

No doubt much depends upon the breed when in a state of domestication; but there is a wonderful disposition to accommodate themselves to circumstances, in the greater number of the race; and when we refer to other countries in which dogs are either in a state of nature, or have been neglected and allowed to run wild, we find that they also partake of the characters of the places where they reside. It is this readiness with which this genus of animals yield to every kind of circumstance, whether that circumstance tend to improvement or deterioration, which renders the progressive history of the dog so utter an impossibility; for though we meet with wild breeds in various parts of the world, which are savage in their dispositions, and exceedingly difficult to be tamed; yet these are just as likely to be the descendants of races which were once tame, as the best bred dogs are to be the descendants of races once wild.

The dog is at all events an old inhabitant of the world; and perhaps there is no animal more generally distributed. Whether dogs existed in a wild state at any period of European history we have not the means of ascertaining; but it is certain that they were in Europe at times long gone by, when the state of the country was very different to what it is at present; for their bones are found in those deposits which contain the remains of the rhinoceros, the tiger, and the hyæna; and though we cannot form very correct notions of how animals not now found in any but warm countries should have once inhabited both continental Europe and the islands, yet we have in India an example of the same races of animals living at least in the near vicinity of each other. But there are many links wanted in the chain before we can in a satisfactory manner connect this oldest epoch of canine story in Europe with the present history of the race.

The uses of this race of animals are so well known, that it is needless to mention them; but still it is doubtful whether they be turned to exactly the most profitable account; and while the savage and his dog are much more nearly upon a par in point of understanding, than any other man and any other animal,

yet it is doubtful whether the dog has had his fair share of the advantages of civilisation, so as to be able adequately to perform his part in the labours of civil society. In the very lowest state of society (we speak of nations, and not of individuals or classes in the same nation,) the dog is, of course, a hunter for his master; and in the forest, and even in the flood, the dog is by far the more independent and the more successful hunter of the two, and could subsist a good deal better without the man than the man could subsist without him.

As society advances a little, the dog becomes an animal of draught; and we find him employed in this state by the people of the extreme north, both in Asia and in America; and as those very northerly tribes are not exactly inhabitants either of the land or of the sea, but rather of the line where these meet, at least during the time that the snow is on the ground, they, of course, can make use only of an animal that can subsist upon such animal food as they can then obtain from below the ice. In some of the southern islands the dog is bred for another purpose. In New Zealand, for instance, there are two species or varieties of dogs,—a large one, which is left free to seek his own food in the woods, as he best may, and a smaller one, which the natives keep in a state of domestication. The large one howls at the approach of the New Zealanders; and all dogs which are not recognised by man as associates in some way or other, growl, or howl and yelp, rather than bark as dogs do in a domestic state. This change of the voice of the dog in consequence of domestication, is an exceedingly curious matter; but it is a fact, and barking is among dogs as much an effect of civilisation, as correct language and eloquent speaking are among men. There is still a closer similarity. The style of the language, not the mere propriety of the words, but the tone in which they are uttered, is no bad index to the general character and disposition of human beings; and so in like manner there is no better indication of the general character of a dog than his voice. The larger dog of New Zealand is not, however, useless to the inhabitants of that country, for it is their principal animal food. Dogs are also eaten by many of the islanders in the Pacific Ocean; and in China they are regularly fattened for the table, and their flesh sold in the butcher's shops. It is also mentioned as an instance of the wholesomeness of dogs' flesh, that the celebrated Captain Cook was mainly recovered from a very severe illness at sea, by the broth and flesh of a dog.

Indeed, there is no reason why these animals should not be cultivated as articles of food in every country. It is a pretty general law in the wholesomeness of animal substances, that if the labour of the animals is not too severe, so that their muscular fibres are thereby rendered too rigid for mastication, their flesh is juicy and racy, and easy of digestion, very much in proportion as they are carnivorous. This holds especially in the case of *gut-birds* and *gizzard-birds* among winged game, and even among the fishes, the few which eat vegetable matter are not nearly so good or so wholesome as those which not only eat animal food, but eat one another. A cod, for instance, is a very king of cannibals, and yet he is a most valuable fish; and the prince of our river fishes, the salmon, is so fond of eating up his smaller associates in the stream, that he may be caught by an imitation of one of them made of a bit of wood and painted. In

spite, therefore, of all our prejudices, and prejudice of some sort or other lies at the bottom of all our self-inflicted miseries and privations—in spite of prejudice, it is really a grave question, and one in which we have the analogy of nature pointing to the affirmative, whether the dog ought not to be regularly bred and fed for the table, as a matter both of good taste and of sound domestic economy. As matters stand at present, it is pretty well understood that all dead dogs are not thrown away, but that not merely the humbler classes, who must be contented with a penny pie or a twopenny sausage, but more dainty palates, are, every day that the sun rises, fain to comfort their stomachs with some such viand as a "savoury *pâté*," containing a portion of a dog, and it may be with a portion of a cat, which cat may have been doomed to suffer the torture of St. Bartholomew at the hands of some cat stealing and skinning hag.

These matters are at least worthy of some consideration, the more so when we call to mind how comparatively few of the vast numbers of the young of those very fertile animals are brought up alive, and how many of them are cast away almost as soon as they are dropped, and thrown on laystalls and in ditches, and not unfrequently in the streets of the most crowded neighbourhoods, offending the eye, and tainting the atmosphere with corruption and disease. And it must be that the taint of such exhibitions fall more heavily than upon the mere atmosphere, because they display a recklessness for animal life which is more numerous in its instances, more loathsome in its displays, and every way more revolting than even that brutal cudgelling of donkeys which some of our legislators have seen meet to select as the special subject of their wisdom. We do not commend the beating of the animals in question, nor would we be understood as wishing to say anything in disparagement of that wisdom—that strong impulsive gravitation of sagacity by which any one subject is chosen in preference to another as the butt of experimental legislation. But, when we compare the two cases together, it is impossible not to see that there is an occasional attempt made to strain at the gnat and swallow the camel.

The disregard of animal life, more especially canine life, which is produced by this incessant murder of the innocents, is much greater than that resulting from any other cause; and it has this enormity in it, that it goes directly to corrupt the very young, and give them countenance and encouragement in the perpetration of cruelty, and of cruelty to that race of animals which, being more directly the associates of man than any other animals, should not, in a pet individual, or even in any dog considered as property, or of whom any one can say, "*my dog*," and quote the adage, "Love me, love my dog,"—not in any of these lights, but generally as a race, and because of the superior endowments with which, as a race, nature has furnished them, it is our first duty toward animated nature to foster and cherish them; but, instead of this, we are strangely taught that it is matter of course, nay, matter of duty, to take them in their helpless state and drown them in cesspools or kennels, or batter them about in the street with more gratuitous cruelty than we would ever think of battering that which never had any life.

Any ignominy offered to the body of that which once was alive, whether the living thing is an elephant

or a gnat, or any thing within the possible range of the scale of animated being, gives a taint to the mind of deeper enormity, because more direct and more lasting in its consequences than many are aware of. The body of every animal is all that, as a substantive existence, is palpable to our senses; in fact, it is the animal to our understanding; for, though we see the action of life in the living animal, we do not see the life itself; therefore, we never can divest the body of an animal, or even a fragment of one, of that association with life which is grounded upon all that we can possibly observe. Wherefore, every indignity which is wantonly, and in the spirit of triumphing over it, offered to even the mutilated fragment of an animal, tells as a step in cruelty towards the whole of animated nature, and towards man himself among the rest. Even the boy who kicks about the head of a pullet, or the foot of a lamb, which has been thrown into the street as useless, is taking one step in cruelty; and it only requires a sufficient number of steps, however small they are individually, to debase him to the commission of murder or parricide.

As this question, or rather the many important questions which this view of the subject opens up, are new, it may be necessary to caution the reader, who has been accustomed to only the common biographical gossip, or the systematic dreams and conjectures on the natural history of the dog, that this bears more directly on the spirit of the part of that history which will come within the scope of reason and certainty, than anything else which we could say on the general subject; while, in addition to this, it bears very strongly upon one of the most important questions in human conduct, both in an individual and a national point of view; and we have taken it in conjunction with the cruelty practised towards the donkey tribe, in order that the ethical part may thereby be rendered more clear and more striking.

In the first place, this cruelty is done to the animal in a state so young, that it can have done no harm, and might be urged on to do good by kind treatment; whereas, in the harsh treatment of the donkey, there is generally some sort of plea of urging it on to speed, and therefore the cruelty here becomes cruelty only by being excessive; whereas the other is entirely gratuitous cruelty in the very smallest atom of it. In the second place, the cruel treatment of the donkey presupposes that there is a feeling of the present usefulness of the animal; and this, again, requires that the person who perpetrates this kind of cruelty is more advanced in life, and also in vice, than the mere children who perpetrate that other cruelty, which society, with one consent, look upon as a very innocent matter of course. Now, there is always more harm done by corrupting the innocent, than by plunging those who are already initiated a little deeper into vice.

So, also, when we look at the youth, the infancy we may say, of the puppies and kittens which are thus daily destroyed, we find that this tendency to disregard animal life, and therefore to treat animals, including human beings, with cruelty, operates against animals when they are in their most helpless, though, at the same time, their most interesting state. There is no question, therefore, that this wanton destruction, in their helpless days, of those animals which stand to man in a relation of companionship so much closer, and more nearly equal, than is found in any

other case, must have the effect of producing indifference to human children; and this is the gravamen of the evil, both in the conduct of the grown up, toward children, and in the conduct as between child and child. It is in early childhood, far more early than we are in the habit of supposing, that the die of human destiny is cast; and if we habituate the young from their infancy to scenes of cruelty, and cases of uncalled for indignity offered even to the dead bodies of helpless and unoffending animals, we may rest assured that we are shaking with more perilous and certain destruction the two main pillars which uphold the fabric of a sound and wholesome population, than by any single perpetration by the random villains of mature age, which will occasionally spot and deform even the best societies. This must suffice for the moral argument, though it is eminently deserving of far more, and might be made the principal theme of as useful a book as ever was written by man. But we must shortly advert to our proper subject, the physiological view of the case, which is, however, inseparably connected with the moral one.

As we have already seen, in our brief notice of the countries where dogs are found, they are distributed over the whole earth, from the equator to the thick-ribbed ice at the poles, and to the remotest isles of the ocean, often where there are no mammalia except themselves, except it may be some rats, or other murine animals; and, though it is incidental, yet it is proper to add, as a corroboration of what we are about to state, that the incredible numbers, and the wonderfully rapid breeding of those small animals, offers another subject well worthy the attention and the profoundest examination of every one who wishes to look on the works of the Almighty with an eye of usefulness and gratitude. We have seen, also, that the dogs can accommodate themselves more completely to circumstances than any other race, more completely than man himself. In, or nearly approaching to, a state of nature, they may be said to be tempered to every wind of heaven—proof to all temperatures—invincible by fatigue, and patient and enduring under hunger. They are, in short, the mammalia of the greatest labour; and one little dog will perform greater feats in the sum total of activity, during a single day, than the strongest lion in the wilds of Africa could endure in a week. Besides, the foot of the dog is for the earth only, to run, to walk, to leap, or to unearth his prey, or dig, or otherwise trim his habitation. In point of fecundity, dogs are also exceedingly prolific, and they are no more seasonal in their breeding than the human race are. We have said that a litter consists of about a dozen sometimes, and there is no doubt that, with proper treatment, it might amount to this at all times, which might be averaged at something like at least a tenfold increase in the year, after making ample allowance for contingencies.

That there is purpose everywhere in nature, any one who is not grossly ignorant must admit. But, here is an animal, more completely distributed over all the earth, more completely adapted to all change of circumstances than any other creature upon the earth, endowed with more sagacity than any other creature upon the earth, not excepting even man himself, if he neglects the cultivation and use of his mind, and capable of breeding more rapidly than any other creature of the same size:—here is, in short the chief jewel in nature's living casket. Can we

suppose that there is no purpose here? Is it consistent with any thing else which we see in nature, that that animal, which is endowed and furnished above all other animals, should be the only one which the Almighty has thus bountifully endowed and furnished, but all in vain?

It is impossible to come to any conclusion so absurd as this, and therefore we must look abroad in nature, and examine what purpose those animals are intended to serve in wild nature, or in countries which have all the richness of virgin soil. Then, if we are able to see our way clearly in this part of the inquiry, we have still another branch remaining, which is highly important, as tending to prove that uselessness to man forms part of the original design which runs through the whole system of nature: and, besides its value in a merely natural history point of view, it is a very strong collateral proof of the truth of the book of Revelation, because it shows that the dominion said to have been given to man is no emanation of human vanity, but a real declaration by Him who cannot lie: "God said, Let us make man in our image, after our likeness: and let them have dominion over the fish of the sea, and over the fowl of the air, and over the cattle, and over all the earth, and over every creeping thing that creepeth upon the earth. So God created man in his own image, in the image of God created he him; male and female created he them. And God blessed them, and God said unto them, Be fruitful, and multiply, and replenish the earth, and subdue it: and have dominion over the fish of the sea, and over the fowl of the air, and over every living thing that moveth upon the earth. And God said, Behold, I have given you every herb bearing seed, which is upon the face of all the earth, and every tree in the which is the fruit of a tree yielding seed: to you it shall be for meat. And to every beast of the earth, and to every fowl of the air, and to every thing that creepeth upon the earth, wherein there is life, I have given every green herb for meat: and it was so. And God saw every thing that he had made, and behold, it was very good."

Such is the original declaration; and the benediction of the whole being "very good" involves in it the notion of the general purpose and adaptation running through the whole, fitting all the individual parts for each other, and the aggregate for rational man, as the means of knowledge and the subject of enjoyment.

From what we know of countries in a state of nature, we observe, that in them the working of nature is everywhere in excess; they are clothed with thick forests, the action of which keeps up a continual evaporation and precipitating of moisture by the air; and as the whole of the vegetation which results from this great energy of the powers of nature is adapted for being food to some living creature or other, the quantity of life existing in such countries is beyond what we can well imagine, if we did not actually see it. It is not the mere surface only which is inhabited, for the trees of the forests are tenanted to their very tops, not only with the smaller kinds of living creatures, but with tree birds and tree mammalia, up to the maccaw, which feeds on the topmost fruits, and the sloth, which keeps down the exuberance of the topmost leaves, clinging to the twigs, and back undermost, grazing against the sky, as if it were a sort of ruminating animal turned upside down.

It would be impossible to enumerate all the details

of this exuberance of nature in the early ages of countries, and in all probability before they became the abodes of the human race; but we have, in those memorials which remain buried in the ground, the clearest evidence that such has been the state of many parts of the world in which the natural vegetation has given place to that which man cultivates for his use; and the elephant, the rhinoceros, the large species of stag, and those older animals of more singular forms, and some of them of more ample dimensions, together with those remains of plants which are buried in the soil, clearly show that, even to high latitudes, even the northern hemisphere, this vast exuberance of nature has at one time been general; and, as the remains of man have never been met with in those sepulchres of the times of old, we may reasonably conclude that this state of things was actually anterior to the peopling of the several regions with human beings.

In a state of things where production was so much in excess, it is natural to suppose that destruction must have been equally so, for the two go hand in hand; and the excess of life is really an excess of change, the transference of organic matter from the body of one living creature to that of another. Now, as the earth can be cleared of animal matters only by the labours of animals which prey upon animal substances, and as the habit of the cat family is to lie in wait and prey chiefly upon living animals; and further, as their structure adapts them rather for great momentary efforts than for continued exertion, they are fit only for keeping down the excess of living animals, and that only in particular situations. But, in such a state of things as that which we are considering, the number of dead animal substances with which the earth must have been strewed, and some of which must have been buried under the earth by the deposits left by the waters, there appears a very obvious necessity for a large supply and general distribution of those animals which belong to the dog tribe, and the other divisions of the great genus *Canis*, the fox, the hyæna, the jackall, and the wolf. We accordingly find that these animals have been very numerous in almost every part, at least of the eastern world, though some of them, as the hyæna, have long perished from the northern parts, and others, as the wolf, are fast disappearing.

But, when we take note of the places where these animals are still to be found, we perceive that they are, generally speaking, countries in which there is a strong action in nature, and a proneness to return to the wild state. We are, in the meantime, concerned only with the dog; and the chief places where dogs are found in a wild state are those in which, if culture is even for a short time neglected, in consequence of hostile devastation or of any other cause, the surface is speedily overrun by thick forests or tangled jungles. Those places are India, some of the eastern isles, and many of those in the Pacific.—Every one who has at all attended to the subject must be aware how speedily every neglected spot of India, which is at all within the reach of the periodical rains, is converted into jungle. A single year suffices in many situations to bring a covering of bamboos at least sixty feet high; and as the larger species of cats are adapted for acting on the margin, and in the open glades of the forests, where, though they require cover for their concealment, they also require scope for their spring, it follows that the beating of the forest must

be left to predatory animals of different structure. So also those larger cats cannot prey on wide plains, because they have no concealment in which they can lie in wait; and, therefore, a race of animals to scour the grounds are there required, not only to clear away the decaying substances, but to keep down the numbers of the browsing animals, and of those birds which seek their food upon the ground. In all such situations we have the proper work cut out for the genus *Canis*, though, of course, the tribes of that genus are adapted to different haunts, and possess different habits. What they were originally we do not exactly know; but from their superior sagacity, and the ease and speed with which they adapt themselves to circumstances, it is easy to see that they are exactly the animals to conform their habits to every change of place, and thus to preserve their existence, after those races which, though more powerful in the individual animal, and also in the individual effort, are much less capable of enduring changes.

It is farther worthy of remark, that animals of this tribe have greater adaptation to all varieties of prey, as well as greater aptitude for all varieties of food, than any other of the predatory tribes; their social habits, and the readiness with which they collect at the sound of each other's voices, make them a match in their collective capacity, for any animal which we could suppose to inhabit their common localities. These localities are the intermediate ones, neither the marshy banks of the water nor the bleak hills; and as the more powerful of the pachydermatous animals, such as the elephant and the rhinoceros, are found in the marshes, which are also the resorts of the larger of the genus *Bos*, the dog tribe can always muster in sufficient numbers to master any animal which they have in general to encounter, and as they have more staunchness than any other animals whatever, the killing of a portion of their numbers by the animal attacked, does not turn them from their purpose.

Nor is their habit of miscellaneous feeding of less service to them. This varies in the several tribes, and also in the several varieties of the same tribe, or even with change of circumstances in the same individuals; but, generally speaking, they can eat that prey which they have previously killed, or they can, in case of necessity, eat the most offensive garbage; and also, in case of emergency, subsist in whole or in part upon vegetable substances. They have also some skill in what we may call animal medicine; for when a dog gets diseased either from improper food, or from a surfeit, to which latter he is often subject after long fasting, he knows as exactly the vegetable substance which will set him to rights, as a human *gourmand* of experience knows what to order from his apothecary under similar circumstances.

It is in different parts of India chiefly that the dog is still found in what may be considered a perfectly wild state, or living in the woods toward the mountains, without any apparent disposition to approach the habitations of the human race; and those which have this habit, are still very retired, so much so as to be not very often seen, though they are known to exist, and that in considerable numbers, all the way from Nepal to the southern heights, and probably to the extremity of India, in all situations where there is sufficient cover for them; but though these dogs are well known, and have been seen and described by Europeans, more especially since Indian zoology has been so laudably and so successfully prosecuted by

British officers, especially those at the out-posts, and detachment stations in the wilder parts of the country, still, with all the knowledge that has been acquired, it is impossible to say whether those dogs existed originally in the mountains and forests of India, or have been allowed to escape in the course of some of those wars by which that country has been so often wasted. We shall have occasion to mention the appearance of this race, when we come to give our list of the leading varieties, so that all we require to do here is to mention that no particular conclusion can be drawn from these regarding what may be the actual habits of dogs in a state of nature. There are other ownerless dogs in the Indian villages, and also in the towns, which resemble more in their manners those varieties which live in the service of man; and these are more social than the dogs of the hill forests. They are advantageous rather than otherwise; because they come and assist the adjutants and other large birds in clearing away the refuse, which otherwise infects the air in an Indian town or village. In this operation they are assisted by the jackalls, which, though they do not make their appearance during the day, begin to yelp in the neighbouring thickets as the dusk sets in; and come during the night to perform their labours, which are far from being without their value.

The circumstances now mentioned with regard to India tend to show the natural uses of the dog in tropical climates; and this is about the utmost extent to which we can go on that part of the subject; because every where else the dog is to some extent or other associated with man, and made to render some sort of service at the bidding of his master. In the more thinly inhabited countries which are wooded, and consequently contain numbers of small quadrupeds, there are many of those half-domesticated dogs which seek their prey by ranging ownerless in the woods; but, generally speaking, they are of the same variety with those that obey human masters. The islands where the larger breed of dogs is kept, or at least captured as game, are almost the only places, with the exception of India, where the wild rangers of the woods and the domesticated ones are of different varieties; and, as the wild dogs there are sought after for food with nearly the same eagerness as game is in this country, they may be considered as in part answering the purposes of flocks and herds to the inhabitants.

In the rest of the world, the other members of the genus *Canis* come in the place of the wild dogs which have been mentioned; and in the extreme north the foxes and wolves, are very abundant; the latter especially are described as being, in the Esquimaux country, the determined and destructive enemies of those domestic dogs which are so eminently serviceable to the people there.

In more advanced states of society the uses of dogs are so familiar to every one, that it is unnecessary to repeat them; but the probability is that enough is not made of the strength and power of enduring fatigue in those animals. It is true that they are used for drawing trucks and small carriages; and though very many of them are in the hands of persons who do not treat them kindly, yet they have more apparent zeal in the performance of their work, and do more of it in proportion to their size, and the cost of their maintenance than any other of our working animals; and they at the same time act as

guardians of property, when their masters have occasion to leave it with them. Considering these things, it would, perhaps, be desirable to pay a little more attention to the kind of work which dogs could be made to perform, and the best modes of training and applying them to the performance of it. We shall now give very short notices of the leading varieties. This is a part of the subject in which it is not possible to be systematic, for those reasons which have been already explained, and therefore we shall take the grouping of M. F. Cuvier, which is founded chiefly upon the greater or less elongation of the muzzle; but there is little dependance to be placed on the accounts which authors give of the way in which the varieties have been produced, either by change of climate or otherwise.

Dogs, of the first division, have the muzzle considerably elongated, and the capacity of the cranium comparatively small; many of them are very handsome in their forms; but they are not accounted so intelligent as some of the others.

Dogs, of the second division, have their muzzles shorter than those of the first, and the capacity of the cranium much larger in proportion; among them are to be found the species which are most serviceable to man, and we may mention the shepherd's dog as an instance.

Those of the third division have the muzzle still shorter; and they are, generally speaking, stouter made than any of the others, and some of them are more ferocious.

The character on which these divisions are founded is a very imperfect one: and the varieties in each, in some instances, differ more from each, both in appearance and in character, than those of the different divisions. It may generally be said that the long-nosed varieties bite by snapping, and give a very powerful bite from the length and quick motion of the jaw; but they do not keep their hold; that those of the third division bite by seizing and retaining their hold, and performing a good deal of their operations by shaking their prey, while they retain a firm hold with the teeth; and those of the second division incline more to the one mode of biting or the other, according to circumstances.

1. LONG-MUZZLED DOGS. The species which are most nearly in a state of nature belong to this division, and we shall take them first in order.

THE WILD DOG OF NEPAL (*Canis primævus*). This variety, which was first accurately described by Mr. Hodgson, extends over a very large portion of India; and as the country is inhabited by many races, it is known by different names in different districts. In Nepal and the adjoining countries where it is found upon all the lower ridges of the Himalaya, from the Sutledge to the Burhampootra, it is called *Bûansû*; in Bengal it is *Dhole*; and with the Mahrattas of the Deccan, it is *Kolsur*. Over so wide a range as fifteen hundred miles in latitude, and more than a thousand in longitude in some places, it must have considerable climatal differences; and there seems also to be some slight difference in its appearance upon the elevated grounds, and in the valley of the Ganges; but all its more essential characters are the same wherever it has been observed; and one of these characters is peculiar, the want of the second tuberculated tooth in the lower jaw. Mr. Hodgson is of opinion that this is the parent stock of all the domesticated dogs; and it is for this reason that he has

given it the name of *primævus*; but the hypothesis is a mere assumption, which does not admit of proof, and therefore the name is somewhat objectionable. The chief climatal difference is that in the elevated and comparatively cold country of Nepal, it has much thicker and stronger fur, and is darker in the colour than in the more southerly parts of India.

This dog certainly belongs to the long-nosed division; for the character of that division consists more in the compressed form and small capacity of the skull, than in the mere elongation of the muzzle. Its nose is not very sharp; its eyes are obliquely set with round pupils, and brown irides. The ears are long, erect, and a little rounded at the tips. The body is rather slender, but deep in the chest; and the legs are long, very strong, and rather thick; the tail is tapering, and borne with no recurvature. The neck is long. The whole character has, indeed, a considerable resemblance to that of a Persian greyhound, in a rude and savage state, and exposed to the vicissitudes of a very variable climate. The colour is, generally speaking, a sort of reddish brown, a little darker toward the tip of the tail, and also between the eyes and nose.

These dogs prey equally during the night and during the day, but their chief dependence seems to be upon the scent: they hunt in small packs of eight or ten; and when in pack they are described as giving tongue in a sharp savage bark, unlike that of any domesticated dog, or of the fox, or the jackall; but when they pursue their prey singly, they only utter an occasional growl. They are animals of great vigour and perseverance, and seldom fail in running down antelopes, deer, and other swift-footed game. As we have already mentioned, this species is wild as well as fleet, and therefore it is seldom seen. When a pack are met with, they do not attack human beings, and thus they are quite harmless to the inhabitants; but when they are assailed, they defend themselves, and turn on their assailants with great courage and vigour. When old ones are taken they do not appear to be susceptible of acquaintance with mankind; but when the young are reared in a kennel with other dogs, they recognise their masters and associates, and evince nearly the average intelligence of the usual sporting breeds which are used for running down game.

The *Pariah dogs* which we have mentioned as abounding in and about the villages, have sometimes been referred to this division; but they have many more of the characters of the more capacious-headed dogs of the second division; so that, though in some respects they stand intermediate between the present variety and the various bred dogs of India, it does not appear that these can be considered as bearing any general relationship to them, though it is not unlikely that there may be crosses and mongrel breeds. The *Pariah dogs* themselves are, indeed, a mongrel race; and it cannot well be otherwise; for they mix freely, and without quarrelling with the domestic dogs.

All the native dogs of India, we may remark, appear to be different from any of the European breeds; though among them there are hairless races something like those which are found in Egypt and the parts adjacent.

THE MALAY DOG seems to be nothing else but the wild dog of India, farther changed by still greater difference of climate; and as it is pretty generally

understood that the eastern islands even as far as the Archipelagos of the central Pacific, it is highly probable that the dogs there are still originally of the same variety.

**THE AUSTRALIAN DOG OR DINGO.** This seems still, in its essential characters, to be the same dog; and as there is no placental animal of nearly the same dimensions in Australia, and the Malays have long frequented the northern parts of that country, it has in all probability been imported by them; though

The Australian Dog.

as the natives of Australia had no memory or tradition beyond their personal observation when they were first visited by Europeans, it is not at all likely that they could have remembered the importation, more especially as their topographical knowledge appears just as limited as their natural history. The following is the description of the Australian dog: the head is much elongated and compressed, and tapers abruptly towards the muzzle, having much the appearance of a fox, with short erect ears. In the general proportion of the body he resembles the shepherd's dog. His body is thick with hair; his tail bushy; the hair is of two sorts, one woolly and grey, the other silky and of a deep yellow. The colour is deepest on the top of the head, and on the upper parts of the neck and tail, and the back; the under parts of the neck and tail are paler; the muzzle and face and inner side of the hams are whitish. The tail has eighteen vertebrae (dogs in general have nineteen). The length of the body from the point of the nose to the commencement of the tail is two feet five inches. This dog possesses great agility, and is full of courage; when running he carries his head up and his tail raised or extended horizontally; and he is very voracious, seizing upon every kind of animal food that comes in his way. According to the description, the dingo is altogether rather smaller in size, shorter in the legs and neck, and by no means so fleet as the wild dog of India; but still the differences in these respects are not sufficient to refute the notion of both being originally the same race; and we may see why they should be different, both in appearance and character, when we reflect on the difference between the countries which they inhabit. From the great numbers of deer, antelopes, jungle fowl, and game of all sorts, India is a remarkably good dogs' country; and we have experimental proof in the fact of there being two unreclaimed races in supplement to all the tame ones. Australia, on the other

NAT. HIST.—VOL. II.

hand, is just as bad a dogs' country as we could well suppose. Most of the small animals are climbers and even a sort of fliers, or leapers a great way from branch to branch by the help of the extended membranes attached to their legs; they also live in hollow trees, and places where dogs cannot easily get at them; and thus the only game which is left for the dogs is the kangaroo, which is a fleet jumping animal, far from numerous, and capable of breaking the skull of a dog by the stroke of its immense claw, when it kicks out in running. These may be among the reasons why the dingoes were originally found almost wholly in attendance on the bivouacs of the natives; and it also explains why this animal, which is said to have been a favourite with the poor natives, has become a notorious sheep biter, and even an enemy to domestic dogs, since sheep and other European animals were introduced into the colony. On the first introduction of sheep into the highlands of Scotland, about the time when the old practice of honourable cow-stealing by the men began to fall off, the curs of many places became notorious sheep-stealers; and there are perhaps no dogs which will not kill sheep when pressed for food, if they have not been taught the contrary.

**THE AFRICAN DOG.** The native dogs, which are in a state of semi-domestication among the rude nations of Africa, appear to be of nearly the same race as those which have been already noticed, only by being more domesticated their colours are more variable. Their habits are not much better known than the general characters of the countries in which they reside. The following are some of the particulars which are detailed. The wild dogs of Lower Guinea go out to hunt in large packs, and when they meet with a lion, tiger, or elephant, in their course, they set upon him with great fury, and usually overcome him. In these encounters they often lose a number of their pack. They do little or no damage to the inhabitants. They are red-haired, have small slender bodies, and their tails turn up upon their backs. The wild dogs at the Cape of Good Hope also range in large packs, and clear the whole country where they abound of all the wild beasts, and even the domestic flocks belonging to the several districts. What they kill they carry to a place of rendezvous, but allow the Europeans and Hottentots, who follow them, to take what they think proper without resistance. The Hottentots eat the flesh they thus obtain, and the whites salt it for their slaves.

**SOUTH AMERICAN DOG.** When America was first visited by Europeans, the Indians, both of the south and the north, were in possession of dogs in a half tamed state, and agreeing in many of their characters with those dogs of the eastern continent which have been described. Since then the numbers both of Indians and of dogs have been very much thinned in all the better known parts of the country; but they are still to be met with, and in the wilder places where the Indians have retained their old habits, they are still in possession of the dogs.

The South American dog resembles the wild dogs of India rather more than those of the Asiatic isles, of Australia, or of Africa. The muzzle is rather slender, the ears short and erect, and the hair pretty long, especially that on the tail. The prevailing colour is grey with a tinge of brown on the back, a yellowish tinge on the under part, and ochre-yellow spots on the flanks. In the South American forests, where

peccaries and other small mammalia are plentiful, these dogs abound in the wild state, lodging during the day in burrows, which they dig in the ground, and seeking their food in the night. The old ones are not susceptible of attachment, but those which are taken young can be so far tamed that they are not disposed to join their fellows in the woods; but they are not very sagacious or very tractable. The temptations are so great, owing to the abundance of food, and the close and cool cover during the burning heat of the day, in the thick forests of America, that it is difficult to keep any predatory animal out of these forests; and in Surinam and the adjacent settlements, where, in consequence of the number of rats that infest the sugar manufactories, cats are in much request as domestic servants, the people are obliged to cut their ears close by the head in order to keep them at home. This has the desired effect both in the dry weather and in the rain, as the leaves and branches tickle the inside of the ear in the one case, and the rain gets into it in the other, both of which is very much disliked.

**NORTH AMERICAN DOG.** This variety differs a little from the former; its expression is milder, and he is understood to have a keener scent, and to be more active in the chase, not being so much a dog of the woods as the South American, and being under the necessity of chasing swifter-footed game.

From these varieties we can form some idea of a dog in something like a state of nature; and it is worthy of remark, that though these dogs inhabit regions which are almost the opposites of each other in longitude, and are found both to the north and to the south of the equator, yet there is a very great family likeness among them; so much, indeed, that we can hardly regard them as any thing else than climatal varieties. They are probably the most tropical of all the dogs in their present distribution; though it is inferred from the shape of the bones in the fossil specimens which have been met with in Europe, that this description of dog, or a variety nearly approaching to it, was the one which lived coeval with the more powerful carnivorous animals, and the larger pachydermatous animals in that part of the world. This is rather a curious fact in natural history, and would lead us to infer that certain species or varieties of animals have, in the course of ages, belonged as much to eras in the history of the world as to geographical positions.

Those which we have enumerated, with shades of difference in other localities, which would have been much too minute for popular purposes, are all the dogs which we consider as remaining in any thing like an original state, that is, a state in which their manners and their forms have not been to a great extent modified by the treatment which they have received from their human masters. Or, if they are dogs which have been left to themselves, then they have been so left long enough for acquiring a far more uniform and unchangeable character in their localities than those dogs which are in a state of complete domestication. We shall now give a short enumeration of the leading domesticated ones which belong to the first division, or those with the elongated muzzle, and diminished capacity of skull, acuteness of scent, and tractability and sagacity.

There are two sub-divisions of these domestic varieties, one of which, the greyhound of the Highlands of Scotland, or, perhaps, the Albanian dog,

is the type; and another, of which the common greyhound is typical. The chief distinctions of character between these are, that the first hunt their prey either singly or in packs, and can find it by the scent as well as the eye, though not very readily; and the second hunt singly, and find their prey almost exclusively by the eye.

**THE HIGHLAND GREYHOUND.** This is a very powerful dog, equally staunch and faithful; and, when the Scottish mountains swarmed with stags and roes, it was held in high estimation, as being capable of following the deer over surfaces too rough and fatiguing for the ordinary hounds of the low country. The

The Highland Greyhound.

general aspect of the Highland hound is commanding and fierce. His head is long, and muzzle rather sharp; his ears pendulous, but not long; his eyes large, keen, and penetrating, half concealed among the long, stiff, and bristly hair, with which his face is covered; his body is very strong and muscular, deep chested, tapering towards the loins, and his back slightly arched; his hind quarters are furnished with large prominent muscles, and his legs are long, strong-boned, and straight—a combination of qualities which gives him that speed and long duration in the chase for which he is so eminently distinguished. His hair is wiry and shaggy, of a reddish sand-colour, mixed with white; his tail is rough, which he carries somewhat in the manner of a staghound, but not quite so erect. This is the dog formerly used by the Highland chieftains of Scotland in their grand hunting parties; and is, in all probability, the same noble dog used in the time of Ossian. The Scottish highland greyhound will either hunt in packs or singly. A remarkably fine and large dog of this description was a long time in the possession of Sir Walter Scott, bart., and was a most appropriate guardian for his unique and magnificent seat at Abbotsford. This splendid dog was presented to Sir Walter Scott, as a mark of the highest respect and esteem by the late chieftain, Macdonell of Glengarry. He preserved this race of dogs with much care; and, in order to prevent the degeneracy which arises from consanguinity, he was in the habit of crossing the breed with the bloodhound from Cuba.

and also with the shepherd's dog of the Pyrenees, which is distinguished for its size, beauty, and docility. Sir Walter Scott's Maida was the offspring of a sire of the latter species, and a dam of the Scottish highland race, and certainly was one of the finest dogs ever seen in that country of the kind, not only on account of his symmetry of form and dignified aspect, but also from his extraordinary size and strength.

This fine specimen of the dog probably brought on himself premature old age, by the excessive fatigue and exercise to which his natural ardour inclined him; for he had the greatest pleasure in accompanying the common greyhounds; and, although from his great size and strength, he was not at all adapted for coursing, yet he not unfrequently turned, and even ran down hares. Maida lies buried at the gate of Abbotsford, which he long protected; a grave stone is placed over him, with the figure of a dog cut on it by Mr. John Smith of Melrose, and bears the following inscription:—

Maida, tu marmorea dormis sub imagine Maida  
Ad Januam domini. Sit tibi terra levis!

This powerful and splendid variety of dog was, in the olden time, employed in hunting the wolf, as well as the deer; but the circumstances of the Scotch highlands have changed, the wolf is no more, and the deer is so rare in most places that it ceases to be an object of sport, except to the few who have it as property. The stocking of the hills with sheep has also dislodged the deer, and rendered the deer dog a forbidden visiter. Gentler sport has succeeded, and the soft sportsman of the south, with his pointer and his Joe Manton, have come instead of the driving dog and the daring highlander.

**THE IRISH WOLF-HOUND.** This race has also become nearly extinct, though there are still a few. It was, probably, larger than the highland greyhound, yet it still bore a considerable resemblance. The occupation of this variety is also gone; for there are no deer in *fera nature* in Ireland, and through some mismanagement, dreary and wasteful bogs have come in the stead of her forests, and the memorials of her deer must be sought under these wasteful and neglected accumulations. The following is probably the last general description, from nature, of the hound.

In 1790, Mr. Lambert saw eight of them in the possession of Lord Altamont. They were the sole remnant of their race, which had then degenerated: the hair was short and smooth, brown and white, or black and white. One of the largest dogs was sixty-one inches long from the muzzle to the point of the tail, which latter was, of itself, seventeen inches and a half in length. The ears were six inches long and pendulous. The height from the toe to the top of the fore shoulders, twenty-eight inches and a half; the circumference of the breast thirty-five inches, and of the belly, twenty-six. All were good tempered; and in former generations the race are said to have borne a great resemblance to the greyhound. If this latter fact is well authenticated, it throws some light upon the progressive history of this first division; for the dogs of this subdivision stand something intermediate between the greyhounds, properly so called, and the wild dogs; and so, if there is a return from the greyhound to the type of this subdivision, there might be a return in this to the type of the wild dog.

There are dogs evidently resembling these in other countries, such as the large and rough greyhound of Russia, and that of the low lands of Scotland; but

a particular account of them would not add much to the natural history of the genus.

**ALBANIAN DOG.** If the wolf dogs of Ireland and the Scotch Highlands were celebrated in the middle ages, the Albanian dog was not less so in the classic times of old. They are the veritable hounds of the Goddess Diana; and whatever it may make with reference to the goddess, it is good evidence of the excellence of the dog, that one presented by the immortal huntress to Procris, her favourite, was so staunch, that it never missed its prey. These appear to have been dogs in high estimation, through all the mountainous parts of Greece, and the breed is still preserved, especially in the wild country after which the animal is named. This dog is about the size of a mastiff, his hair is of a very fine consistence, very thickly set, resembling fur, and of a long and silky texture, generally of different shades of brown; his tail is long and bushy, which he carries somewhat in the manner of a Newfoundland dog; his legs are strong, shorter, and with more bone than those of the greyhound, on which account he seems formed for strength rather than for excessive speed. The head and jaws are elongated, with the nose pointed, something like that of the Greenland dog, but rather longer. This dog in former times was used in hunting the wild boar and the wolf, as well as in fighting; and was also reared in pastoral districts to protect their folds from wolves and thieves. We may naturally expect that there should be some climatal varieties in other parts of Europe of a dog which has been so long known to history. One of these probably is

**THE SPOTTED DOG, DALMATIAN, OR HUNGARIAN DOG.** This is more an ornamental than a useful dog; as it is soft in its manners and far from being intelligent; but it is very handsome and very good-natured, and therefore it is much used as an attendant on carriages. It is so well known as to require no further description. In form, this dog bears a slight resemblance to some of the hounds, or the smooth pointers, but he has none of their valuable qualities.

**THE FRENCH MATIN.** This dog is very different from the last mentioned, and possesses properties in some respects superior to any other dog of the division, on which account he is a great favourite in France, where his fidelity and his courage equally recommend him. His general characters are,—the head elongated, and the forehead flat; the ears pendulous toward the tips, and similar to those of the greyhound; the hair is generally of a yellowish fawn colour, with blackish, slate-coloured, oblique, and parallel indistinct rays all over the body. He is a very active and muscular dog, standing about two feet high, and three feet long. He is possessed of great courage, and displays much ferocity in attacking wild boars and wolves, in the hunting of which he is frequently used, and evinces great perseverance and eagerness in the chasing of them. The principal use of the matin in France is the tending of flocks, in which service he has all the qualities of the shepherd's dog of this country; he is likewise employed as a house-dog, and is extremely assiduous and watchful in that capacity, protecting his master's property to the last extremity. In France he is held in higher estimation than any other of the watching or guarding dogs. But we must turn to the varieties which are still more deficient in scent and sagacity, but have that deficiency compensated by additional swiftness, great quickness of ear, and considerable acuteness of

vision. The general name of these is *greyhounds*, though that name is also given to the large and powerful wolf-dogs of the former subdivision, which have both the body and the muzzle much elongated, and are remarkable for their speed when on the chase.

There is this difference between them, however, that the dogs formerly mentioned, are much stronger, do not, in general, run so swiftly, but can continue much longer.

**THE GREYHOUND.** The greyhound is the very model of animals for symmetry ; and while his limbs are peculiarly muscular, though lightly made, there is no dog, and perhaps no animal, which has such elasticity of the spine. In many of the cat tribe that organ can be powerfully exerted for a short time ; and in some of the *viverride* it acts powerfully for a continuation of leaps ; but in no animal do the spine and the limbs play so beautifully to each other as in the greyhound. The general character of the animal agrees with this elasticity of motion ; for there are few which are so actuated by fits and starts. The figure of the greyhound is so peculiar, so little likely to be confounded with that of any other dog, that it is quite unnecessary to go into any description of it. In ancient times the greyhound was reckoned a very valuable present, by the ladies especially, who regarded it as a very gratifying compliment. As far back as the time of King Canute, it was enacted by the forest laws, that no person should presume to keep a greyhound under the degree of a gentleman ; the sovereign regarding that animal as being peculiarly suited only to a person of elevated rank. In Charles the First's reign, greyhounds were held in very high estimation. The Isle of Dogs, which is now converted into the reservoir for the West India shipping, derives its name from being the receptacle of spaniels and greyhounds of Edward the Third ; and was selected from its contiguity to Waltham and the other royal forests.

Much of the superiority of our present breed of greyhounds we owe to the judgment and perseverance of Earl Rivers and others.

*The Scotch Greyhound*, which is in all probability the *gazehound* of England, is larger than the smooth greyhound of England and the warmer parts of Europe, and it is also of larger size, though not so elegant, and probably, for a short distance, not so fleet. It is generally understood that this was the dog employed in driving the deer in the moors of the south of Scotland, and the north of England, at the time when that was so principal an occupation of the barons ; but in the pure state this hound is now comparatively scarce.

*The Turkish Greyhound* is comparatively a small species with very little hair, so little that it does not hide the black skin. Its ears are not quite so pendent at the tips as those of the greyhound, properly so called ; and it is so insignificant in size, that it is only used as a pet. There is, however, a greyhound of the chase very much used in some places of the south-east of Europe ; and there is another in Persia, which resembles the wild dogs more than the wild dogs of Europe. The little *Italian greyhound*, which is very handsome, is used as a pet in many parts of Europe ; and it is a very lively little creature, but not remarkable either for attachment or sagacity. Such is a short outline of the leading varieties of dogs in the first or long-nosed division.

II. DOGS WITH THE MUZZLE OF MEDIUM LENGTH. This section also admits of several subdivisions,

according to the uses to which they are applied, and the properties which fit them for those uses. The principal subdivisions are hunting dogs, and dogs which, though they have a propensity for hunting, are more used for domestic purposes, or in some way to assist man in his labours.

Of the hunting dogs there are two or three farther subdivisions, the chief of which are dogs which are used in the chase, and dogs which are used with the gun ; the last of which are most generally employed, except by those who sport on a large scale. The first are hounds of various descriptions ; the others are setters, spaniels, and a variety of others. We shall begin with

**THE BLOODHOUND.** This hound is, or rather was—for in most European countries, at least, the breed is nearly extinct—the best on the scent of all the coursing dogs, and perhaps, also, the most staunch and persevering in pursuit of his game. When his human associates happened to be of mild dispositions and contented themselves with using him only in the legitimate way in which a sporting dog should be used, he was mild tempered and exceedingly tractable ; but the very virtues of this dog were perverted through the vices of his masters ; and down to a comparatively recent period, and perhaps, in some places even at the present time, the bloodhound has been trained to hunt human beings, and so add to the horrors of war, and the relentless cruelties of extermination. This dog has been used for these purposes in different parts of the world ; so that of the few which remain, there are several apparent varieties.

At one period of the world's history, the commencement of which was in ancient times, bloodhounds were much used in Britain, and the breed is said to have been very superior. According to Strabo, British bloodhounds were used as auxiliaries in the wars of Gaul ; and there is no doubt that this prostitution of a noble animal to the basest of purposes, is the reason why, from time immemorial, this dog has had a bad name, and that "bloodhound" has been the appellation for such monsters of the human race, as could not be done justice to by any epithet drawn from the very worst vices of mankind.

The Bloodhound.

The following particulars will throw some light upon the character of an animal now little known, and also the uses to which this animal was applied :—In

old times, when possessions were insecure, the bloodhound was employed to trace out the thief, and recover the stolen goods; so that he would swim a river in course of the pursuit, and immediately recover the footsteps of the culprit on the other side, never ceasing to follow him until he was taken. Thus this animal is put under the protection of the most ancient laws, which enact, "that no person should stop or disturb a bloodhound or man passing with him, to follow thieves, or take malefactors." Theft was also so common in this island, that a person denying access to the hound was held participant in the crime. There is little doubt that it was known on the continent, and also in England; but the Scottish bloodhound, which is said to have been of large size and elegant proportions, was the most celebrated of all. Conrad Gesner, who wrote nearly three hundred years ago, has preserved a figure of the Scottish bloodhound, which, he says, was transmitted to him by Henry Sinclair, Dean of Glasgow, a distinguished character of his era; and Hector Boyce affirms, that it was of a red colour, or black with small spots. There was some difference between it and the English bloodhound, though the properties of the latter were also eminent.

Of the atrocities which were committed in ancient times by using bloodhounds against the human race, no accounts have come down to us; but unfortunately we have specimen enough of what can be perpetrated in this way, in perhaps the blackest page in a volume of human history, no part of which is very bright. This is the history of the conduct of the christian white men of Europe toward the unoffending red men of some parts of America, and, more so, to few of the hapless sons of Africa who had been captured and carried away to endure all the miseries of colonial slavery. Even the great Columbus himself, in order more completely to subdue the lawful owners of the island of Hayti or St. Domingo, carried out with him twenty-four bloodhounds as auxiliaries in his unjustifiable war upon the harmless and newly discovered natives. It is possible that all the occasions upon which bloodhounds have been used against negro slaves which have taken refuge in the mountains have not been recorded; but a single specimen of their use by the French, some time previous to the island being wrested from their power, will suffice. In the last war carried on against the revolted negroes, or Maroons as they were called, they employed bloodhounds regularly trained against them, and they are even said to have had the barbarity of throwing their captives to the dogs to be devoured alive. In training the hounds to this inhuman pursuit, we are told that they were confined in a kennel sparrowed like a cage, and sparingly supplied with the blood of other animals. The figure of a negro in wicker work, stuffed with blood and entrails, was next provided as they grew a little older, and occasionally exhibited in the upper part of the cage: the dogs ferociously struggled against their confinement, and as their impatience increased, the effigy was brought nearer and nearer, while their usual subsistence underwent still greater diminution. At length it was resigned to them, and while voraciously tearing it up, and devouring the contents, the caresses of the keepers encouraged their perseverance. Thus their animosity to black men was excited in proportion to their attachment to the whites; and they were sent out to the chase when their training was considered complete. The miser-

able negro had no means of escape: he was either hunted down and torn to pieces, his wife and children sharing perhaps his calamity, or, if taking refuge on a tree, he was betrayed by the yelping of the bloodhounds into the power of his more savage pursuers. This, however, was not the full extent of the evil. "But, indifferently kept in the neighbourhood of Cape François, the dogs frequently broke loose, and infants were devoured in an instant from the public way. At other times they proceeded to the neighbouring woods, and surprising a harmless family of labourers at their simple meal, tore the babe from the breast of its mother, or devoured the whole party, and returned with their horrid jaws drenched in the gore of those who were acknowledged, even in the eyes of the French army, as innocent, and therefore permitted to furnish them with the produce of their labours."

The stages of cruelty are progressive; and those who delight in the torture of animals, will soon be indifferent to the sufferings of mankind. Accordingly, the ruder nations universally enjoy ferocious contests, and are gratified with the sight of blood. Lions, tigers, and elephants, have been encouraged to tear each other in pieces, where mutual antipathies ceased to operate; but to make use of that quality in the dog, which fits him especially for being the servant of man—to make use of that quality as an instrument of the most inhuman torture upon those who were already suffering misery enough, is beyond a parallel in the annals of atrocity.

In hunting, which was his legitimate work in those days, when much of the country was in the condition of forest and chace, deer numerous, oxen few, and sheep not introduced in many places, the proper function of the bloodhound was to find the game rather than to run it down; and it was because he could find the scent or *slot*, as well as keep it till he came on the game, that he was called the *slot-hound* or *slenth-hound*. He was also called the *slow-hound*, in which the epithet *slow* may have in part been a corruption of *slenth*, though it also related to the rate of his following as compared to that of the deerhounds, which, as keeping more on the view than on the slot, run with much more velocity. The staunch perseverance and continued following of the bloodhound compensated for his inferior swiftness, as without him the deer could not, in many cases, have been found; and if the deer threw the staghounds out, the bloodhound was ready to find him again. The perfection to which he could be trained for the slot was very wonderful, and forms a very curious portion of the doctrine of the sense of smell. To prepare him for his labour, his nose was either rubbed against the kind of animal in quest of which he was to go, or with the hand of a man which had been so rubbed. This being done, the hound was let slip; when he instantly began beating for a slot; and, though the scents of ever so many animals lay on his beat, he never followed except on the right one. It was in this that the great superiority of the bloodhound consisted. Many other dogs of the chase can be trained to one kind of game; but there were none who could be trained to any kind in a summary manner like the bloodhound.

It would be very desirable to know upon what this capacity of being able to distinguish species in scents depends; but the question is, we fear, beyond the possibility of solution.

THE STAG-HOUND is now the largest variety of

hound in Britain, and the numbers are very few; and for *bona fide* stag hunting we may say there are none, though there is an occasional run "for sport" at a carted stag. Numerous packs are used upon these occasions, which are got up more to show off the pack than for any other purpose. The stag-hound is a large, handsome, and tractable animal, but much inferior, in point of nose, to the bloodhound.

**THE TALBOT.** This name is usually associated with that of the "Old English" hound; but, as is the case with the "gazehound," it is not satisfactorily known what particular animal is meant. "Talbot" is certainly an old English name, in the same way as *Matin* is a French name. We suspect, however, that calling the talbot the old English hound is just about as correct as it is in the manufacturers of dictionaries to call the *matin* the mastiff. The probability is, that talbot was a general name for hounds, whether they were used in the chase or as watch-dogs, when those hounds were not trained to some one particular sport.

**THE FOX-HOUND.** This species may be said to be, at the present time, the favourite hound in Britain, and great attention has been paid to the breeds; so that, whether in private kennels, or in subscription or country packs, there is perhaps no country in which this variety of dog has been brought to so much perfection as in England. These dogs have a keen scent, and the style of their running is very fine, and especially the air with which they carry their heads.

Where the ground will admit of it, fox-hounds run more in rank than any other dogs, and sometimes the column presents a pretty long front in line. The nose of the fox-hound is rather long, and, in proportion to his body, his head is small; his ears are pendulous and long, but not so much so as those of either the stag-hound or bloodhound. His chest is deep, his legs are very straight, his feet round and well proportioned, his breast wide, his back broad, his shoulders are placed well back, his neck thin, his tail bushy and thick, which he carries high when in the chase. His colour is generally white, variously patched with black brown and liver colour in different parts of the body. Fox-hounds, and indeed all hounds which are kept for hunting in packs, can be regarded as in only a state of partial domestication. They are, as it were, the military of the race, take the field in squadrons, live apart in their kennels or barracks, and do no civil duties.

**THE HARRIER.** This species resembles the fox-hound, only it is smaller, less powerful, and, generally speaking, not so ferocious. Harriers are more generally kept in Britain than fox-hounds, there being much more scope for hare hunting than for fox hunting; for, as the country becomes more cultivated, foxes diminish in number, while, under the same circumstances, hares increase. Harriers do not run so majestically as fox-hounds, but their cry is much more musical and agreeable.

**THE BEAGLE.** This is smaller than any of the other varieties of hound, and by no means so fleet in the chase. It, however, possesses qualities which are in some respects superior, being more sagacious, and possessing a much better nose, so that it can follow on the scent in situations where the harrier would be thrown out.

Besides those which have been noticed, there are several other denominations of hounds; but the above must suffice as a general sketch of the race.

Somewhat allied to hounds are the *Terriers*, a

smaller breed, but much more strongly made, more courageous, better mouthed, and, along with great sharpness of bite, possessing no inconsiderable share of the bull-dog property of retaining their hold. We believe they are not used in packs, or much in the chase in any way, their chief use being to bring burrowing animals out of their earths; and so staunch are they at this, that a terrier will often draw a badger of more than his own weight. Terriers attack all wild animals indiscriminately, and they are not to be turned from their purpose either by largeness of size or by rankness of smell. They are, properly speaking, the *vermin* dogs; and though they are very expert at unearthing, and very forward in attacking foxes, hares, and rabbits, they are equally efficient against badgers, polecats, weazels, rats, and mice. On account of their latter propensity, they are very much used about farms, and about houses generally; and, though they are somewhat irritable, they make most efficient watch-dogs, as they are not only very forward to attack, but very formidable, and exceedingly difficult to be vanquished. There is no doubt that a sufficient number of them would be able to overcome the largest wild animal; and they have a sort of natural propensity to the hog tribe, and might, even in smaller number than some dogs of larger size, be efficient against the wild boar. The writer of this article knew a gentleman who had a very fine Scotch terrier, which not only cleared a large farm, and also the farm-yard, of all vermin, but acted as cattle-dog or sheep-dog, as occasion required, and was so vigilant and so formidable a guardian, that no intruder could with impunity either invade the house or trespass on the farm, but used successfully to repel the inroads of a very powerful and fierce boar which used to come in a furious and formidable manner, so much so, indeed, that he often threw the labourers in the fields into the greatest alarm; but if *Trap* happened to get notice of the invasion, the boar, though very large, much in the shape of a wild boar, and of that brindled colour which indicates the nearest approach to that formidable animal, paid severely for his temerity; the dog, who had been trained to keep animals in their right places, but to kill nothing except game and vermin, made no direct attack on the life of the boar. He laid hold of him by the ear, and that hold he kept till the boar, though much stronger and far heavier than the dog, was so completely subdued, as that *Trap* could lead him by the ear to his own place of abode. The dog had seldom occasion to lead him half way; but he used to watch his motions, and if the boar offered to return, the dog instantly went to meet him, and so punished his other ear, that there was no need for a second warning, at least during the next week.

One of the principal uses of the terrier as a hunting dog is to accompany the fox-hounds; and in cases where all the earths are not carefully stopped, a labour which it is not easy to perform in places where there is much cover, the terrier is indispensable, because his assistance is necessary in unearthing the fox.

**SCOTCH TERRIER.** This dog is generally low in stature, very seldom more than thirteen or fourteen inches in height, with a strong and muscular body, and short stout legs. His ears are small and half erected. His head is large in proportion to the size of his body, with the muzzle considerably pointed; he has an exceedingly acute scent, so that,

with certainty, he can trace the footsteps of all other animals. They are variously coloured, but generally of a sand colour, or black. Those which are thus coloured are certainly the most hardy, and can be depended on more. When pied or white, it is a rare sign of the impurity of the breed. The hair of the terrier is hard, long, and matted, over almost every part of the body. His bite is extremely keen. There are three distinct varieties of the Scotch terrier, namely, the one above described; another about the same size as the former, but with the hair somewhat flowing, and much longer, which gives a short appearance to the legs. This is the prevailing breed of the western islands of Scotland. The third variety is much larger than the other two mentioned, varying in height from fifteen to eighteen inches, with the hair very iron and hard, and not so long as that of the others. The best bull terriers have been produced from this breed. Amongst the higher order of sportsmen the terrier is preserved in its greatest purity, and with the utmost attention; and it seems of the greatest importance not to increase its size, which would render him unfit for the purposes in which he is employed, that of entering the earth, and driving other animals out of their burrows, for which his strength, make, and invincible ardour, peculiarly fit him.

**THE ENGLISH TERRIER.** In appearance this is a much more handsome dog than the Scotch terrier, being much smoother in the coat, and much more lively in the colours. Generally speaking, the back, the sides, the neck, and the top of the head and the tail, are black; and the belly, the throat, and a spot over each eye, clear reddish brown. The hair over the whole body is very strong, but short and glossy; the head is small, and the muzzle of moderate length; the ears are also small, partially erected, and turned over at the tips; the tail is rather short, and blunt at the end, so as to appear as if it had been shortened artificially; it is carried partially elevated, but not recurved. Dogs of this description are very common, and vary much both in their size and quality. The difference between the smooth glossy coat of this terrier, and the rough and wiry one of the Scotch, is another instance, in addition to that of the greyhound of the two countries, of the effect of a colder climate in roughening, and of a warmer climate rendering more smooth, the coverings of these animals; and it will be borne in mind, that there is the same difference in the wild dog of India, as found in the southern parts of that country, and in the mountains of Nepâl.

There are several other terriers named and described in the more extensive works on sporting dogs; but, though they differ in appearance, from climate and other circumstances, their general characters are everywhere nearly the same.

We shall now give a short account of those dogs which are generally used in shooting, and which are remarkable for the fineness of their scent, for their docility, the gentleness of their manners, and the strength of their attachment to man. Many of them are chiefly used in the capture of ground birds, such as partridges and grouse, and others chiefly in fowling for water birds; but they are so docile, so gentle in their manners, and often so handsome, that very many of them are kept as house or pet-dogs, and not a few are carriage companions of persons of high rank; and when they are so, they are honoured with a place inside, and not left to run like the spotted dog.

Each dog is in its element, however, in this; for, while the great attachment of the riding dog is to the riders, that of the running dog is to the horses. When used in sporting, some of these dogs start or spring the game, while others merely point at it. The dogs which start game are generally called spaniels, but sportsmen often name them according to the kind of game which they are employed in raising.

**SPANIELS.** The chief difference between spaniels and the other dogs used in shooting is, that the spaniel gives tongue the instant that he scents the game, and by that means raises it, so that the sportsman may take aim at it on the wing, which is the only gentlemanly way of shooting winged game. They are comparatively weak dogs, and their bite is not very formidable, but they are exceedingly active. The *Springer*, or true spaniel, used in springing game, bears a considerable resemblance to the setter in shape, but is much smaller in size. The colours are red, liver-coloured, yellow, and white; their ears are very long, soft, and pliable, and covered with long and very silky and delicate hair; the tail hangs down, and is bushy, but it is in continual motion while they are hunting. The *Cocker* is much smaller, but far more lively and active than the spaniel, and he is so fond of sport, that he can be kept running the whole day long without apparent fatigue. Of the pet spaniels there are many breeds, of which King Charles's, and the Blenheim, or Marlborough, are among the most esteemed. Smaller sized than even these, there is an endless variety, but, except for their beauty and attachment, they are of but small value; though all spaniels, from their restlessness, and the proneness they have to give tongue on the

The Spaniel.

least alarm or noise, make excellent watch-dogs inside a house, they are too feeble and too delicate for being of much value out of doors during the night. There is one variety, however, which is an exception to this, and that variety is,

**THE ALPINE SPANIEL, OR DOG OF ST. BERNARD.** This is a dog far exceeding every other spaniel in size and strength, and also in beauty and sagacity. In the last respect, he is perhaps superior to every other dog. A full-grown one measures six feet form the point of the nose to the end of the tail, and stands at least two feet high at the shoulder. The offices which these beautiful and highly interesting dogs perform are very different from those to which the bloodhound has often been degraded; and the following account of their labours, services, and sufferings, will be read with interest:—

"The convent of the great St. Bernard is situated at the top of the mountain known by that name, near one of the most dangerous passages of the Alps, between Switzerland and Savoy. On these regions the traveller is often overtaken by the most severe weather, even after days of cloudless beauty, when the glaciers glitter in the sunshine, and the pink flowers of the rhododendron appear as if they were never to be sullied by the tempest. But a storm suddenly comes on; the roads are rendered impassable by drifts of snow; the avalanches, which are huge loosened masses of snow or ice, are swept into the valleys, carrying trees and crags of rock before them. The hospitable monks, though their revenue is scanty, open their doors to every stranger that presents himself. To be cold, to be weary, to be benighted, constitute the tide to their comfortable shelter, their cheering meal, and their agreeable discourse. But their attention to the distressed does not end here. They devote themselves to the dangerous task of searching for those unhappy persons who may have been overtaken by the sudden storm, and would perish but for their charitable succour. Most remarkably are they assisted in these truly Christian offices. They have a breed of noble dogs in their establishment, whose extraordinary sagacity often enables them to rescue the traveller from destruction. Benumbed with cold, weary in the search for a lost track, his senses yielding to the stupefying influence of frost, which betrays the exhausted sufferer into a deep sleep, the unhappy man sinks upon the ground, and the snow drift covers him from human sight. It is then that the keen scent and the exquisite docility of these admirable dogs are called into action. Though the perishing man lie ten, or even twenty feet beneath the snow, the delicacy of smell with which they can trace him offers a chance of escape. They scratch away the snow with their feet; they set up a continued hoarse and solemn bark, which brings the monks and labourers of the convent to their assistance. To provide for the chance that the dogs, without human help, may succeed in discovering the unfortunate traveller, one of them has a flask of spirits round his neck, to which the fainting man may apply for support, and another has a cloak to cover him. These wonderful exertions are often successful; and, even where they fail of restoring him who has perished, the dogs discover the body, so that it may be secured for the recognition of friends; and such is the effect of the temperature, that the dead features generally preserve their firmness for two years. One of these noble creatures was decorated with a medal, in commemoration of his having saved the lives of twenty-two persons, who, but for his sagacity, must have perished. Many travellers who have crossed the passage of St. Bernard since the peace have seen this dog, and have heard, around the blazing fire of the monks, the story of his extraordinary career. He died about the year 1816, in an attempt to carry a poor traveller to his anxious family. The Piedmontese courier arrived at St. Bernard in a very stormy season, labouring to make his way to the little village of St. Pierre, in the valley beneath the mountain where his wife and children dwelt. It was in vain that the monks attempted to check his resolution to reach his family. They at last gave him two guides, each of whom was accompanied by a dog, of which one was the remarkable creature whose

services had been so valuable to mankind. Descending from the convent, they were instantly overwhelmed by two avalanches, and the same common destruction awaited the family of the poor courier, who were toiling up the mountain in the hope to obtain some news of their expected friend. They all perished. A story is told of one of these dogs, who, having found a child unhurt, whose mother had been destroyed by an avalanche, induced the poor boy to mount upon his back, and thus carried him to the gate of the convent. The subject is represented in a French print."

The *WATER SPANIEL* is even a more attached animal than any of the land ones. There are two principal varieties, the *great* and the *small*, or *poodle*. They do not differ very much in appearance, only their heads are rather larger and rounder than those of the land spaniels, and their hair is longer, and more curly and silky.

The following is one of the most remarkable instances of fidelity in this most attached of all the canine race; and though it has been frequently in print, we give it without the least hesitation:—

"A few days before the overthrow of Robespierre, a revolutionary tribunal had condemned Monsieur R., an ancient magistrate, and a most estimable man, on pretence of finding him guilty of a conspiracy. Monsieur R. had a water spaniel, at that time about twelve years old, which had been brought up by him, and had scarce ever quitted his side. Monsieur R. was cast into prison, and in the silence of a living tomb he was left to pine in thought under the iron scourge of the tyrant, who, if he extended life to those whom his wantonness had proscribed, even until death became a *prayer*, it was only to tantalise them with the *blessing* of murder, when he imagined he could more effectually torture them with the *curse* of existence.

"This faithful dog, however, was with him when he was first seized, but was not suffered to enter the prison. He took refuge with a neighbour of his late master's. But, that posterity may judge clearly of the times when Frenchmen existed at *that* period, it must be added, that this man received the poor dog tremblingly, and in secret, lest his humanity for his *friend's* dog should bring him to the scaffold. Every day, at the same hour, the dog returned to the door of the prison, but was still refused admittance. He, however, uniformly passed some time there. Such unremitting fidelity at last won even on the *porter* of a prison, and the dog was at length allowed to enter. The joy of both master and dog was mutual; it was difficult to separate them; but the honest jailor, fearing for himself, carried the dog out of the prison. The next morning, however, he again came back, and once on each day afterward was regularly admitted by the humane jailor. When the day of receiving sentence arrived, notwithstanding the guards, which jealous power, conscious of its deserts, stations around, the dog penetrated into the hall, and couched himself between the legs of the unhappy man, whom he was about to lose for ever.

"The fatal hour of execution arrives; the doors open; his dog receives him at the threshold! his faithful dog *alone*, even under the eye of the tyrant, dared to own a dying friend! He clings to his hand undaunted. 'Alas! that hand will never more be spread upon thy head, poor dog!' exclaimed the condemned. The axe falls! but the tender adherent

cannot leave the body; the earth receives it, and the mourner spreads himself upon the grave, where he passes the first night, the next day, and the second night. The neighbour, meantime, unhappy at not seeing the dog, and guessing the asylum he had chosen, steals forth by night, and finding him, caresses and brings him back. The good man tries every way that kindness could devise to make him eat; but, in a short time, the dog escaping, regained his favourite place. Every morning, for three months, the mourner returned to his protector merely to receive his food, and then returned to the ashes of his dead master! and each day he was more sad, more meagre, and more languishing.

"His protector, at length, endeavoured to wean him; he tied him; but what manacle is there that can ultimately triumph over nature? He broke or bit through his bonds; again returned to the grave, and never quitted it more. It was in vain that all kind means were used to bring him back. Even the jailor, who had witnessed the strength of his attachment, used to carry him food; but his affection for his master seemed to strengthen as his frame became weaker; and sometime after he had ceased to take any nourishment, he began digging his own grave in the earth which covered the remains of the object of his attachment, continuing in the feeble performance, till he expired half buried in his master's grave."

There are two very favourite varieties of dogs, which though not exactly spaniels, are yet very nearly allied to them in their attachment, their playful dispositions, and their aquatic habits. These are the great rough water dog and the poodle. The first is a variety of which the origin cannot be very clearly traced; the second is understood to be a cross between the first and the cocker. These two resemble each other in their covering, and also in their fondness for swimming and their dexterity in diving. The hair of both is very long, and if left uncut, twists into pendent ringlets, while the curl on the water spaniel is short and crisp like the curls of a wig. By this means it is easy to discriminate the spaniel from the other two; and the different texture of the hair makes it as easy to distinguish the water-dog from the poodle. The hair on the water-dog is, strong and rough, and that on the poodle very silky, about the same in texture as that of the cocker. They are all sometimes called poodles; they are deservedly favourites as pet dogs; and they are often trimmed lion-wise, with only a mane, a tuft on the tail, and one on each of the heels.

The *water-dog* is a highly useful animal in all aquatic situations or on board ship. He is never so much in his element as when he is fetching and carrying. He brings game to land, recovers light objects that are let overboard at sea, and will plunge into pretty deep water, and fetch a stone from the bottom; they carry gloves, sticks, and other matters, and they will return for any thing if they have been previously shown it. This dog is of various colours, but not unfrequently black, with the hair fading into brown at the points.

The *poodle* is, generally, smaller than the water-dog; and its soft silky fur gives it a more delicate appearance. It is very playful, and swims and dives well, though it is, perhaps, inferior in these respects to the other. It is often of very small size and beautifully white in the colour, with eyes as black as jet, and very intelligent in their expression. In this form it is an especial pet.

**SETTERS AND POINTERS.** The habits of all these dogs are nearly the same; and though they are not so docile, gentle, and affectionate, they are indispensable to all who wish successfully to beat the fields or the moors for sport with the gun. They are dogs of fine scent and admit of very high training. They are silent dogs, and beat or quarter the ground with great activity, discovering the game by scenting the air, standing still at a dead point without moving any part of their bodies when they have discovered it, and after the gun is up and the game down, fetching it to their master. As there is some skill required in breaking or training them properly, a thorough good one is of considerable value. If the dog is not properly trained he is apt to make false points, that is, to point at small birds and other things not worth powder and shot; and not only at these, but also at the forms or places where game has recently been.

The *setter* is understood to be an English dog. It is smaller than the pointer, and not so showy, but it is said to have a better nose, and to be less liable to injury in the feet while beating hard and stony ground. When put to work in enclosures, the setter generally beats round close under the hedges before he begins to quarter the field in breadth. There are two named varieties of setter, independently of the numerous breeds. Indeed, as they are mongrel dogs, produced by crossing, chiefly between spaniels and pointers, the varieties of them may be multiplied without limit. Their hair is, in general, beautifully curled. There is, however, a good deal of trouble in breaking setters, and they cannot be always trusted to after they are broke. Their propensity to stand and point is not pure; for they have it only as they have the blood of the pointer in them; and in as far as they have the blood of the spaniel, their propensity is to give tongue and put up the game. Of course in the natural state of the animal these opposite propensities weaken each other; and it is only by careful training that the one can be rooted out and the other established. But if this is once done, the setter is a very valuable dog; and though smaller than the pointer, it quarters the ground faster, and can continue longer.

**POINTERS.** Of these there are several varieties, independently of breeds. In their general form, pointers bear some resemblance to hounds; but the muzzle is shorter, the ears smaller, and partly erect and partly pendulous; and the difference of appearance between them and setters may be observed in the portion of the spaniel character which is necessarily possessed by the latter. The *Spanish pointer* is the finest of the whole, and the greatest care is taken by those interested to preserve this breed as pure as possible. His natural tendency is to be silent and to point; and therefore he not only requires much less training than the others, but is much more sure and steady in his point; and he is at the same time very obedient and docile. He has the disadvantage, however, of being very delicate, both in respect of fatigue and of management; and thus, though a very fine dog, he is rather an expensive one. As a dog for the rough moors, he is inferior to the setter, as he is unable to endure the fatigue of a long morning, and his feet are very liable to be injured. The *English pointer* is a cross between the Spanish and fox-hound and harrier; and though in consequence of this he is more difficult to break than the Spanish, he is upon the whole a more valuable dog for general purposes. He is very handsome, remarkably docile,

and when he is properly trained, his nose is very good. In the south of Germany there is a very small breed which is an exact miniature of the English pointer. The *Russian* pointer is very like the Spanish one in form, except a remarkable peculiarity in the nose, which is so deeply cleft as to appear cut in two, and to procure him the name of the double-nosed pointer. There are various other pointers, and the varieties of the English one in shape, size, and colour, are almost endless.

We shall now briefly notice a few of those dogs of the second division, which are used for domestic purposes, though some of them are ready enough to take game if it comes in their way.

**THE NEWFOUNDLAND DOG.** This is a noble animal, and, with the exception of the water spaniel, it takes the water much more readily than almost any other dog. The feet of this species are webbed. Indeed, when of pure blood, the Newfoundland is the prince and honour of the race. His size and strength are great, and his look dignified, so that those who are not accustomed to him are apt to be afraid of his approach; but he is exceedingly mild, and has at once the most beautiful and expressive eye of all the race. Unless under very extraordinary circumstances of provocation and necessity, he is never the aggressor; and though many large dogs are very prone to tyrannise over the smaller ones, he has no such habit, but will bear considerable indignity rather than fight with any dog of insignificant appearance. A full grown Newfoundland dog of the pure breed, and that has received proper treatment, measures six feet and a half from the nose to the tail, the length of that appendage being two feet, and very handsome both in its form and in the style in which it is carried.

The Newfoundland Dog.

From the one fore foot to the other, over the shoulders, five feet eight inches; girth behind the shoulders three feet four inches; round the head across the ears two feet; the upper part of the fore leg measures ten inches; the length of the head fourteen inches; and from his feet being webbed, he can swim with great ease, and for a very considerable time. His body is covered with long shaggy hair; his legs are feathered, and he has an extreme villous tail which is curvilinear. The Newfoundland dog is but of recent introduction into this country from the island whose name he bears, and may be considered as a distinct race. He is docile to a very great degree, and nothing can exceed

his affection. Being naturally athletic and active, he is ever eager to be employed, and seems delighted in performing any little office required of him. From the great share of emulation which nature has given him, to be surpassed or overcome would occasion great pain to him. On every emergency he is active, the friend of all, and is naturally without the least disposition to quarrel with other animals; he seldom or never offers offence, but will not receive an insult or injury with impunity. Such is the capacity of his understanding, that he can be taught almost any thing that man can inculcate, of which his own strength and frame are capable. His sagacity can only be exceeded by his energies, and he perseveres with unabated ardour in whatever manner he is employed, and while he has a hope of success he will never slacken in his efforts to attain it. The amazing pliability of his temper peculiarly fits him for man's use, and he never shrinks from any service which may be required of him, but undertakes it with an ardour proportionally to the difficulty of its execution. He takes a singular pride in being employed, and will carry a bundle, stick, or basket, in his mouth, for miles, and to deprive him of either of these is more than a stranger could with safety accomplish. Sagacity and a peculiarly faithful attachment to the human species are characteristics inseparable from this dog, and hence he is ever on the alert to ward off impending danger from his master, and to free him from every peril to which he may be exposed. From the astonishing degree of courage with which he is endowed, he is ever ready to resent an insult or to defend his friends, even at the hazard of his own life. Inclined habitually to industrious employment, such dogs are as useful to the settlers of the coast, from which they are brought, as our galloway and ponies are to us. It is easy to accustom them to daily labour. From three to five of them are harnessed to a sledge, or other vehicle, containing a load of wood or lumber amounting to twenty or thirty stones, which they will draw very steadily for miles with ease, and will do this without the aid of a driver, when acquainted with the road; and having delivered their burden, they return home to their masters, and receive, as a reward for their labour, their accustomed food, which generally consists of dried fish, of which they are said to be extremely fond. Indeed, the qualifications of this dog are very extensive. As a keeper or defender of the house, he is far more powerful and intelligent, and more to be depended upon than the mastiff, and has been much substituted for him in England of late years; he may indeed with great propriety supersede that breed. For his services upon navigable rivers and as a watch dog, none can come in competition with him; and many sportsmen have introduced him into the field with great success as a pointer, his sagacity and kindness of disposition rendering it an easy task to train him. Although this variety is styled the Newfoundland dog, there is every reason to believe that it was not found in that island when first visited by Europeans; and in corroboration of this it may be observed that it does not resemble the Arctic dogs properly so called, which are dogs with very shaggy hair, and much more ferocious in their dispositions, although, like this one, they are employed in labour. It has been said that this is a cross between some sort of English dog and a she-wolf of Newfoundland; but what species of English dog would, with a she-wolf, have produced a dog of the size, shape, and disposition of the Newfoundland, and at

the same time web-footed, it is not easy to say; and therefore we strongly suspect that the origin of this highly interesting breed must remain for ever doubtful.

**ARCTIC DOGS.** In all those places of the polar countries, near the ice, which are not adapted for the pasturage of the reindeer, the dog is the most valuable domestic animal. These dogs have all a strong family likeness; and they all have the muzzle rather elongated, the ears erect, the legs and loins very strong, and are otherwise fitted for enduring great fatigue. These dogs have been named after the countries in which they are found—the *Siberian dog*, the *Iceland dog*, the *Greenland dog*, and the *Esquimaux dog*; but the differences among them are not greater than we find among dogs of the same nominal variety in this country. In those dreary regions, where winter prevails fully three-fourths of the year, it would be impossible for the inhabitants to exist were it not for these dogs; and the faithful animals, in performing their labours in drawing the sledges over the snowy deserts, are often subjected to the severest privations. Marco Polo, the celebrated Venetian traveller of the thirteenth century, distinctly speaks of a country in the north of Asia, difficult of access on account of the intermediate mud and snow, from which great quantities of furs were carried in vehicles wanting wheels by means of dogs. The information he received on the subject characterises the sledges of Greenland or Kamschatka, now drawn by these animals. In this latter country the species employed is of a middle size, of various colours, white, black, grey, or black and white, of wolfish aspect, yet not unlike the shepherd's dog or its mongrel offspring. Its hair is rough, its tail recurved, and the ears pointed; it cannot be taught to hunt, and never barks, but howls. Though regularly trained to the draught, the dog of the Kamschadale and Greenlander seems less tractable and domesticated than that of civilised countries, proving perhaps how much its nature is modified by associations with man. All that are thus occupied are castrated, to preserve them more under controul. During the prevalence of ice and snow, from five to ten of them are harnessed to a light wicker-work sledge, about three feet long and one in breadth. The driver is supported by a seat a yard above the ground, and the whole frame rests on two curved pieces of wood or sometimes whalebone, which operate as skates in gliding over the frozen snow. The total weight of the sledge does not exceed ten pounds, in which journeys incredibly long are safely accomplished. The harness is made of leather, the dogs are arranged in pairs, commonly with a leather along the whole in front, and are fastened together by straps or reins through their collars, fixed by a hook and chain to a ring in the fore part of the sledge. If the journey be difficult, or the burden heavy, the number of dogs is increased; and when M. Lesseps brought the despatches of La Perouse over land from the harbour of Petrapowloski, thirty-seven dogs were harnessed to his sledge, and forty-five to that of the companion of his journey, the Governor-general Kasloff. Thirty-five sledges were in company, drawn by nearly 300 dogs. But journeys of this description, though generally successful, are not entirely void of danger. The traveller, whose position is sidewise, and not directed forward, must be careful to preserve the equilibrium of so slight a vehicle; if it inclines to the right, he must lean to the left, and his posture must be changed when the

inclination is reversed. The utmost vigilance is necessary not to be overset, and if this accident should occur he must hold vigorously by the sledge, as the dogs once in motion run straight forward, and with greater ardour on their burden being lightened. They are scarce to be restrained on the open way, and on descending deep declivities. Kraschenonikoff affirms that they are liable to be unyoked from the violence with which they rush down. They likewise become unruly on scenting deer, or hearing dogs in the neighbouring villages. Much of the security of the traveller depends on the training of the leader, and the whole are guided by the voice and a crooked stick, without any whip. But the fatigue of long journeys is so great, that the dogs frequently perish under it; food is scanty, and shelter rarely to be obtained. Of the 300 dogs employed by M. Lesseps's party, in crossing the peninsula of Kamschatka, only twenty-seven at last remained; many died of want and exertion, the others, when tied up, ate the cords and harness from hunger, and some devoured the carcasses of those that had perished.

**PASTORAL DOGS.** Though these have not the same strength as the dogs which are used for draught, and are far from being the most handsomely formed of their race, they are intelligent, tractable, faithful, and highly useful in every situation where their services are required. There are many breeds and climatal varieties of them in different countries. In Britain there are two principal ones; the one of them a sheep dog, and the other more of a cattle dog; but as these dogs are kept very indiscriminately by the country people in the less cultivated districts, there are many mongrel breeds which want the more valuable qualities of the true one. In the case of both too, there are two divisions, tending dogs and driving dogs, which have been perhaps separated from each other by the different labours in which they are employed.

In the richer parts of the country, where the land is divided into inclosures, the tending dogs are less wanted; but in the wild parts, where the land is pastured in breadth, and where the labour of the shepherd or the herdsman, in attending to all the individuals of the herd, would be intolerable or even impossible, they are of the greatest value; and neither the proper care of the flock nor that of the herd could be rightly managed without them. They are not so much wanted in those places where sheep and cattle are fattened, because there it is desirable that the animals should be subjected to as little motion as possible, in order that they may be fit for the table in the shortest time possible. In the breeding districts it is different. Proper exercise is necessary to the full development of the animal, and to that soundness of constitution, by means of which alone it can be of the best quality when fattened; and as the pastures there are wide, the dogs are indispensable for fetching in strays, and keeping the flock together.

There is a peculiarity of structure in the feet of these dogs, which is worth attending to, as an instance of how beautifully nature adapts every creature for the office which it has to perform; though this peculiarity is not confined to these dogs, but belongs to them in common with the spaniel, the pointer, and all dogs which have the habit of preying upon ground game without running it down in the chase. This peculiarity consists of a greater or smaller number of supplemental toes or appendages at the posterior part

of the foot, technically known by the name of "dew claws." These are soft and pendent, and do not act by means of muscles, like the toes, properly so called, but are a sort of fringe to the back part of the foot. In walking on hard surfaces they are of no use; and as they are liable to be torn and lacerated in beating among bushes, and thus to cripple the animals,—for wounds in the feet of dogs are more injurious to them than in any other part of their bodies,—they are cut off in sporting dogs when very young; but in shepherds' dogs, and in pastoral dogs generally, they are allowed to remain; and in the hill pastures especially, which are interspersed with bogs, and places between the hummocks of grass which consist of soft and sludgy peat, these dew-claws, by spreading out to their whole length by a little pressure, greatly extend the surface of the foot, and thus enable it to bear up the animal in situations where it otherwise would sink, in the same manner as people furnished with snow shoes, can walk over snowy surfaces, in which, if they had not these means of protection, they would sink knee deep. This peculiarity is found wanting in all the coursing dogs, and in all those which, in a state of nature, find their prey upon the firm ground.

Shepherd's Dog.

In the shepherd's dog, the ears are erect, as they are in the wild dogs, and, as in these, the muzzle is sharp. The character of the coat, too, indicates that they are mountaineers, or tempered to abide the severity of the weather. In all the varieties of dogs which we have had occasion to mention as extending over great range of climate, whether in latitude or in difference of elevation, it will be borne in mind that as we get into the colder climate, whether that is caused by difference of latitude or by difference of elevation, the coat of the animal in the cold climate is long and shaggy in proportion to that of the warm. A very remarkable instance of this may be perceived on referring to the plate of dogs, where the dog of Nepal, or Thibet, and the dog of India, which are really the same variety, are figured. The Indian one will be observed to have a smooth and close coat, while the dog of the mountains is as shaggy as a bear. So also in the dog of the Mackenzie River, which is also figured, the covering will be observed to be particularly shaggy; whereas the very same dog in the warm parts of America has his clothing perfectly smooth. In the shepherd's dog this accumulation of

the fur is most conspicuous on the under part of the tail, the back, and the fore legs; but the production of hair varies considerably in different places; the shepherd's dog of the mountains being much more shaggy than the same animal in the plains. This intelligent and useful animal is one of the most obedient, serene, and placid members of the canine race. He is ever alive to the slightest indication of his master's wishes, prompt and gratified to execute them; and he appears to enjoy the greatest delight when employed in any useful service. By nature formed with an instinctive propensity to industry, he is never more pleased than in exerting his talents for the benefit of man, and in giving constant proofs of his inviolable attachment. The patience, native calmness, and devoted faithfulness of the shepherd's dog, render him insensible to all attractions beyond the arduous duties connected with the flock under his care. When once properly trained, he not only becomes perfectly acquainted with the extent of his beat, but also with every individual in the flock; he will very correctly select his own, and drive off those that encroach on his boundary. This will appear the more extraordinary when we consider the vast extent of country and the numerous flocks committed to a single shepherd's charge, which duty he could not possibly perform but for the invaluable services of this very sagacious animal. A word or signal from him will direct the dog so as to conduct the flock to any point required, and that signal he will obey with energy and unerring certainty. The labour of a shepherd, with the assistance of a dog, is comparatively an easy task; but without one we can hardly suppose an occupation more arduous. Without, indeed, the aid of this animal, it would be next to impossible to collect the flocks in those extensive and precipitous tracts of mountain-land where sheep delight to graze, and which are in many places quite inaccessible to man. The shepherd's dog, from being inured to all weathers, is naturally hardy; and, accustomed to hunger and fatigue, he is the least voracious of the species, and can subsist upon a scanty allowance. If a shepherd is travelling with his flock to a distance, his dog will only repose close to his feet; and should he wish to leave them for the purpose of taking refreshment, he has only to intimate his intention to his dog; and he will guard the sheep in his absence with as much care, and keep them within due bounds, as well as he himself could have done. Although left alone for hours, a well-trained dog always keeps the flock within the limits of a made road, even, should there be no fences; he watches every cross path and avenue that leads from it, where he posts himself until they are all past, threatening every one who attempts to move that way; and, should any of them escape, he pursues them, and will force them back to their companions without doing them any injury. The breed of this dog is preserved with the greatest attention to purity in the north of England, and in the highlands of Scotland, where his services are invaluable. The shepherd's dog of this country, with all his good qualities, in point of size and strength, is still greatly inferior to those of the Alps, and of that extensive range of mountains which divide France from Spain, as well as to the variety which is found in the neighbourhood of Caucasus.—In this country there are two kinds of this dog: that used by shepherds, which is of a small size, and the breed used by drovers and butchers. About London,

and in many parts of England, the drover's dog, which is chiefly used in driving sheep, is without any tail : this, however, is not the natural form of the animal ; for the tail is destroyed when very young, not by cutting off, but by extracting the bone, which is technically called "stringing," and is generally performed by pulling out that part with the teeth. After this the fleshy part of the tail contracts to a mere tubercle, and is wholly concealed among the shaggy hair of the animal. Dogs which are treated in this manner are said to endure much more exertion with less fatigue than those in which the tail is entire ; and whether this be the fact or not, the degree of fatigue which those dogs can undergo is truly astonishing. Nor is their sagacity less wonderful, for they can divide the drove into any sections that may be required, drive one section one way, and another another way, whatever may be the number, and after the sections are once parcelled off to the purchasers, they can bring back again with the most unerring certainty any individual which has left its section, and joined another. These offices are generally performed by barking and manœuvring alone, without touching the sheep with the mouth ; or if that operation be necessary, the dogs merely lay hold of the sheep, and force them into the intended direction, by holding the wool without biting the skin or even separating that portion of the wool of which they take hold.

Indeed, in all situations, the shepherd's dog conducts matters chiefly by his voice, or what may be called the word of command ; and he is not more skilful in giving his own commands than he is apt in receiving the commands of his master. In which way those commands are understood, is no easy matter of explanation ; but the fact is certain, that a skilful shepherd can send his dog, if a thorough bred one, to the flock, a mile distant, on the opposite hill, and make him separate from the rest, and bring any number, and, as it is said, any particular individuals that he may be directed to bring. The matter is entirely above our comprehension ; but the fact is certain, that these dogs know and can distinguish every individual sheep of the flock, to the charge of which they are appointed ; and in situations where sheep are folded for the night, if even one sheep is missing, the dog will, without being instructed, return and beat the pasture for it ; and if he finds that it has stuck in the mire, or otherwise got into any situation from which it cannot extricate itself, he returns to the shepherd, and, by the style of his barking, indicates that assistance is required, and leads the way to the place where the distressed sheep is, with as much certainty as any pilot or other human guide. This peculiarity is not confined to the shepherd's dog ; but belongs to it in common with various others of the more social dogs, or those which are more closely attached to mankind ; and there are innumerable instances of dogs, when they themselves have failed in rescuing persons from perilous situations, going in quest of human assistance, and indicating by the earnestness of their cries, that that assistance was immediately and urgently required. The case of the London firemen's dog, Billy, may be mentioned as a very remarkable one. That animal was the first to find out any fire that occurred ; he collected persons to assist ; and though he of course could not actually put his paw to the engines, yet he was so full of bustle and activity, and so encouraged every one who was working by the earnestness of his commendations, that there is no question but that he was the means of saving a great deal of property ; for

even a dog doing his duty in so disinterested, devoted, and hearty a manner as it was done by honest Billy, was enough to put to shame any one who refused to lend a helping hand. We mention the case of this dog, because it shows that those animals might be trained to far more useful purposes than any to which they are usually applied, valuable as many of these are, and those of sheep-tending, and sheep-driving dogs in an especial manner. When we consider that one good shepherd's dog performs services which could not be performed by twenty shepherds in a flock, which one shepherd can easily manage with the assistance of the dog ; and, when we farther consider that without the dogs, it would require many times the number of men which are now employed to bring sheep to the markets, and divide them off to their respective purchasers, we are within the mark when we say that we eat our mutton full twenty per cent. cheaper in consequence of the labours of the shepherds' and drovers' dogs.

**THE CUR.** This dog's name is rather at a discount, and he is considered a snarling and ignoble animal ; but still he is a very useful and very faithful creature. He is the watch-dog of the cottager, the playmate of cottage children, and the associate and defendant of labouring people and their property ; and while the man is stripped and at work, if his faithful cur, or *colly*, as he is called in some places, takes post upon his coat, that coat is as safe as if it were under lock and key. There is also a softening of the heart produced in the labourer when he shares his lonely meal with his little dog ; and, as the dog is in the field with him in all weathers, wet and dry, it is not easy to say to what extent he cheers and encourages the man, and promotes as well as lightens his labour.

But it is not in such situations alone that this dog is valuable ; for he is in an especial manner the cattle dog, and of the utmost value in all those places where the country is grazed in breadth, because there he brings in the stray cattle with the same certainty and the same success as the shepherd's dog brings in the stray sheep. It is worthy of remark, that those dogs which are useful in the management of domestic animals never attempt to make their attacks on a vital part, or on any part where a bite would be of serious injury. The mastiff flies at the throats of cattle, and the bull-dog attempts to seize them by the nose, and suffocate them, something in the same way as the jaguar is said to do with the wild cattle in South America ; but the curs, and other true cattle dogs, never attack any beast in front. They invariably snap at the heels, and pinch that part which answers to what is called the "funny bone" in the human elbow, and upon which even a moderate pressure with the fingers causes an acute momentary pain. One might very easily suppose that there is an original instinct for driving cattle without biting them in these dogs. When they snap at the heels, they seldom if ever draw blood ; and they snap at the one heel or the other, according to the direction in which they wish to turn the animal. Any one who has attended to the habits of animals must have observed that they always run upon that which gives them pain. If a horse in battle is slightly wounded by a bayonet, he will run upon it to his certain destruction ; and man himself is not exempted from this propensity ; for, if a bayonet once wounds a man in battle, so far as to give him pain, he is almost certain of running himself through upon it.

How dogs become aware of this propensity in animals it is impossible for us to ascertain, because we do not know the notions by which animals are governed in their instincts. Indeed, the subject is one of those upon which all inquiry is vain, inasmuch as we are not in possession of anything similar, in our own experience, which we can compare to it. We know nothing experimentally of the operation of instinct unconnected with reason; and, in consequence of this, we can never come to any satisfactory conclusion with regard to the motives or foundations of action in animals. But, notwithstanding this, the facts are undoubted; and there is no fact better made out, or more wonderful in its cause, than the tact of these dogs in the driving of cattle. If they wish to turn the beast either to the right or the left, they pinch the heel only on that side towards which they wish to turn it, and the degree of their pinching is equal to the right of turning which they wish to effect. The beast also, itself, in so far seconds the action of the dog, because it brings round its head towards that side on which the pain is felt, and the joint action is sufficient to turn the beast fairly round, and force it off in the opposite direction before it has advanced more than its own length. If the object, however, is to drive the beast straight forward, the snapping is made alternately at both heels, and so long as it is continued, the beast advances with a yawing motion, until it is brought to the proper speed in the proper direction, and then the dog ceases to trouble it.

This driving by the heels is a very valuable character in those dogs, inasmuch as it is quite impossible to drive cattle by attacking them in the head. In that case they offer battle, or, at all events, defensive hostilities, from their instinctive tendency to guard themselves from injury in that quarter. Hence, when it is attempted to drive cattle by dogs which assail either the throat or the nose, the cattle are invariably driven wide, or separate from each other, and the labour of the dog is worse than useless.

The cur is, probably, a variety, in part connected with, or derived from, the shepherd's dog; but it differs from the shepherd's dog in its being smooth in the hair, while the shepherd's dog is invariably shaggy. The legs are considerably longer in proportion to the size of his body, which is a good deal larger than that of the shepherd's dog, and is stronger in the make, with the ears half pricked, and a tail having a natural tendency to be short. Great attention is paid to the breeding of this dog in the north of England and southern counties of Scotland, as he is found to be a very useful and trusty servant; and great care is also devoted by breaking him in for that purpose. Being a very sagacious dog, he soon acquires a knowledge of his master's fields, which he watches with the utmost vigilance, and is particularly attentive to the cattle that are in them, watching all their movements and regularly going his rounds; and should any strange cattle appear among the herd, he will fly at them with great ferocity, and force them immediately to quit the pasture they are trespassing on. The general colour of this dog is black and white; but it may occasionally be met with all black, and sometimes it may be found all white. As, however, there is less attention paid in most places of the country, to the purity of this breed of dogs than to that of any other, the mongrels related to the curs, and used instead of them, are exceedingly numerous, so much so, indeed, that no account can be given of them.

There are several breeds of dogs connected with those of the present division, and perhaps, also, with those of the former, which it may be necessary to notice. The principal of these are the following:—

*The Lurcher.* This is a dog which hunts singly, and finds his game indiscriminately by the scent or the eye. It bears some slight resemblance to the hound, but its limbs are shorter and stronger in proportion; its form is much less elegant, and its motions much more slow. The head is thicker and not so much pointed; the ears are short, erect, and half pricked up; and the whole body is covered with coarse and shaggy hair, which is generally either of an iron-grey or a dull sand colour. This is a sneaking species of dog, and prone to lie in wait for his game; and, therefore, he is a favourite dog with poachers, who employ him under cover of night, in the capture of hares and rabbits, and occasionally winged game. He is not much esteemed by regular sportsmen, and his very name is one of dishonour; but within his sphere of action, the lurcher is a very sure and trust-worthy dog.

*The Leynmmer* is a dog whose memory is almost forgotten; he was understood to be the produce of a cross between the greyhound and common hound, or talbot, partaking of the qualities of both with some additional ones of his own in supplement. Indeed, it almost invariably happens that, in cross breeds of dogs, if both parents are thoroughly bred, there are new and often very good qualities obtained by the cross. The leymaner possessed much of the swiftness of the greyhound, together with a keen sense of smell, and he was, perhaps, more hardy than either of the breeds of which he was the joint production. It is, indeed, a very general case that cross-bred animals are much more hardy than either of the parents between which they are crosses; and they are so whether they be what we call perfect animals, as is the case in most if not all of the mongrel breeds of dogs, or hybrids, which do not breed with each other, although they breed back to the pure blood, as is the case with the mule, between the horse and ass. This dog, notwithstanding his strength, his swiftness, and his power of endurance, had some of the stubbornness of the mule about him; and it was necessary to confine him in a thong, and let him slip after the game had started, otherwise he would have run broad, and been quite ungovernable.

*The Tumbler.* This is also a mongrel dog, though of what parentage is not very clearly ascertained. He is considerably less than the greyhound, with a long and lean body, and erect ears, but with the head more resembling the greyhound than that of the lurcher does. Still, however, his action is in many respects similar to that of the lurcher. He does not run his game fairly down in straight forward chase, like the greyhound, but practises arts, and shows a great deal of sagacity in catching it upon the double. In order to do so, and to betray the game into doubling nearer to him than it otherwise might, he counterfeits falling down or being crippled, until the game on the return of the double comes within his reach; and then he pounces upon it with a single bound much greater than that of almost any other dog. It is from this habit of crouching and waiting the double, which he does with great dexterity, that he gets the name of tumbler; and though he is far from being one of the most elegant or graceful dogs in coursing, he is by no means one of the least successful.

*The Turnspit.* It is somewhat difficult to define to what other race of dogs these are most nearly allied. They are, perhaps, the least graceful of the whole tribe. Their bodies are long, their legs remarkably short, and they are prone to become exceedingly fat, as they are very lazy. They have, however, some good qualities. The following are a few of their leading characters:—the head is rather large in proportion to the size of his body: for the most part it has a peculiarity in the colour of the eyes, one of which has the iris of one eye white and the other black. The Turnspit is to be met with of all hues, but the most usual one is a kind of bluish-grey, spotted with black,—sometimes he is found of a slate colour. The shape of the head is something between that of the hound and pointer, with long ears. One variety of the Turnspit has straight legs. He is a bold, spirited, and vigilant little dog; its services in Great Britain at one time were very much valued, but by the invention of machinery his work has been superseded: he is, in consequence, becoming extremely scarce, and in all probability will very soon become extinct, although in Germany and France he is still used in the kitchen. Turnspits that take their hours for labour in regular rotation, know very well how to distinguish the roasting days from the rest; and it is with some difficulty that they can be made to work on the latter, as if they had a notion that it was then a duty that they were not in duty bound to do. Several instances are recorded of dogs distinguishing the days of the week; for in the neighbourhood of some towns there are dogs that regularly repair thither for market days, because they know that they can procure some booty then.

The varieties of mongrel breeds in this division of dogs are, however, endless, so that it would be impossible to give any account of them, though they are all less or more attached to mankind, and capable of evincing affection in some way or other. But in towns, where the breeds of dogs are miscellaneous, these are apt to be mongrel curs, of very vicious character, which do not either benefit their keepers, or tend to place the race in a favourable point of view.

III. SHORT-MUZZLED DOGS. The dogs of this division are different in their characters from those of either of the former; and the differences are so striking, that it is by no means easy to suppose that they are of the same original race either with the dogs that have the elongated muzzle, or with those which have it of medium length. It is somewhat remarkable, that among dogs which are in what may be called a state of nature, there is no approximation to the short muzzle; but the origin of this race is so obscure, that nothing can be said respecting it with any certainty. They differ from each other according to the breeds and kinds as they are described; but there are certain characters which belong in common to the whole of them. They have not the swift motion of the long-nosed dogs, neither have they the affectionate manners and playful dispositions of most of those of the second division; and if the epithet “dog” is to be considered as a synonyme for surliness, this is the division of the canine race which are dogs by way of eminence; and they are the only ones to which the French, who are not unhappy in their nomenclature, give the name of *dogues*. These dogs are often faithful, vigorous protectors of the property of their masters; but they show no kindness or affection. The larger ones are very

formidable, and even dangerous animals; and the small ones, which are sometimes kept as pets, have little feeling of gratitude, and are always snappish to every body except those by whom they are immediately fed; and even to them the attachment does not appear to extend much beyond the selfish consideration of being fed.

The dogs of this division are of no use whatever in the chase, or in any way in shooting or hunting; they are not swift, their noses are very inferior, and their only good qualities are the strength, the severity of their bite, and the firmness with which they retain their hold. As used against domestic animals, in keeping them to their proper places, and turning them in any direction which may be wished, they are not efficient, neither are they safe. They do not drive the animal, as is the case with sheep-dogs and curs, but always attack it in front, attempting to seize its nose or tear its throat. They are, in fact, slaughtering or tearing dogs; and they can be used only in those characters, and not in that of friends, companions, or assistants in any one labour. They are good only for an attack; and, therefore, some of them have been employed in the most cruel and savage of those occupations of the profligate which are very absurdly named sports.

It is a curious fact that dogs of this description should be known only in a state of domestication.—Some of the wild dogs are savage enough in their manners; but there is none of them so savage, and we may add, none of them so destitute of what might be called intellect in animals, as these short-nosed dogs. It therefore becomes a curious question how these races originated, and by what particular kind of treatment on the part of man, all the nobler qualities of the dog were merged in the single one of trustworthy ferociousness. Nor is it less a matter of curiosity, if we could unravel it, to ascertain why, along with this character, dogs of this division should have greater strength and more determined powers of endurance, than any of their more attractive brethren. This question we have unfortunately no means of solving; because, though we know the origin of particular breeds we do not know the source whence they were derived, or the means by which they have been made to differ so much from the rest. It is also singular that, along with this departure from the swift motions of dogs of the first class, and the endearing dispositions of dogs of the second, there should be in this third one an alteration in the form of that most characteristic organ of a dog, the mouth. But such is the fact. These dogs do not bite with the same sharp snap as the others; but in them all there is a disposition to hold on and to shake in pieces whatever they lay hold of. Their object, in fact, appears always to be the mangling and destruction of that on which their anger is directed, and though, in the performance of this, many of them are faithful, it is a faithfulness of ferocity. It is for this reason that they are chiefly employed as watch-dogs; and it is their bad qualities, not their good ones, which are turned to account by their masters. They are, in short, dogs which are wanted only in vicious and depraved states of society; and it does not reflect much credit upon civilised man that there should be no such dogs found among savage nations. If we could ascertain by what means the different breeds which form this section have been derived from the dogs which we know in wild nature, or whether they have been derived at all,

it would be a very curious inquiry, but, unfortunately, we have not sufficient data for such an investigation; but, though we are not acquainted with the means by which mankind has been enabled so to degrade the more generous and noble qualities of the dog, as they are found a great deal in these races, yet there is no reason to doubt that the degradation is the result of human interference. Still, it is a curious matter, that not only the form of the head, and the shortness of the muzzle, but that the whole structure and appearance of the animals, which, judging from what we see in nature, are artificial, should have been altered so as to suit this apparently impressed and unnatural habit. We have no means of unravelling the mystery; but really it is a curious matter, that, along with a cessation of swiftness in the chase, or play as a companion, there should have been imparted to those dogs a strength of body, and a shortness of muzzle, which are not possessed by any of the rest; and these qualities are accompanied by a corresponding expression in the eye and hair of the animals. In the larger kinds, both eye and hair express ferocity, while in the smaller ones the expression is that of indifference or stupidity; and both have the body much more thickly set, the chest wider, and the legs farther apart, than in those of either of the former divisions. There is also a distinctive character in the very covering. None of them have that smooth lengthened and curly hair which is so pretty in the smaller spaniels, and so graceful in the larger ones and the Newfoundland dogs; neither have they that smoothness and gloss which we observe in the terriers (with the exception of the Scotch one), which, of all dogs of the former divisions, perhaps make the nearest approach to the present division, though they far excel them in sagacity. The character of the head is especially worthy of notice. In every dog of the two former divisions, of what breed soever he may be, and whether pure or mongrel, there is a pleasing expression in that part; and even in those species, such as the greyhound, which are the least intelligent, there is always some speculation in the eye—something in the look of the animal, which speaks kindness and companionship; but a dog of this short-nosed species, though he follows his master, feeds at his expense, and fights desperately for or with him, in good cause or in bad, merely glares upon the observer, and has no speculation in his eyes. His services as a guardian or a warrior may procure him respect; but his own looks do not put in any thing like the same claim to kindness or society, which is solicited by a single glance from the other dogs. It is further to be remarked, that the dogs kept by the worthless and profligate part of mankind are almost invariably of this short-nosed kind.

The varieties of those short-nosed dogs are not nearly so numerous as those of either of the former divisions, but as they are dogs which are chiefly bred for sporting purposes, much attention has been paid to the breeds. They may be considered as forming three classes:—first, dogs which are wholly untractable and pugnacious, and therefore never used except as fighting dogs; secondly, dogs which still possessing much strength and ferocity, and not capable of much training and attachment, but which are used as watch dogs; and thirdly, dogs of smaller breed, which are too feeble for doing much mischief, and which may be reckoned the most useless perhaps of all the genus.

**THE BULL-DOG.** This dog in various breeds may be regarded as the fighting dog *par excellence*; and, as the satirist said of the captain—"His very look's an oath," so it may be said of the bull-dog—"his very look's a bite." This dog is low on the legs, and stands rather wide; his chest is deep and also broad; his shoulders and thighs are very strongly made; and the muscles are exceedingly developed, more so than perhaps in any other animal, not even excepting the lion. The head is broad, his nose short, and the under jaw projects beyond the upper, which gives him a very disagreeable and fierce aspect. The eyes of the bull-dog are very prominent and distant, and have a very peculiar suspicious-looking leer, which, with the distension of his nostrils, gives him also a contemptuous look; and from his teeth being always seen, he has the constant appearance of grinning while he is perfectly placid. This is the most unrelenting and ferocious of the canine tribe, and may be considered courageous beyond any other creature in the world; for he will attack any animal whatever be

The Bull-dog.

his magnitude. He is scarcely capable of any education, and is fitted for nothing else but combat and ferocity. The bull-dog takes his name from having been employed in former times in assaulting the bull, and is used for that purpose at the present day in those districts where this brutal amusement is still practised. The fury with which the bull-dog attacks all other animals, and the invincible obstinacy with which he maintains his hold, nothing can exceed. The bull-dog makes his attack always in front; and in assailing the bull, he attempts to seize him by the nose, the lip, the tongue, or the eye. If the dog succeeds in fastening, and the part is tough enough not to be torn off by the bite, the dog will not quit his hold, and cannot be shaken off by any effort of the animal, but will adhere though the other swing him round and round in the air. When they fight with each other, or with other dogs, they are equally desperate in their hold; and when they once fasten they will allow themselves to be bitten ever so severely by another dog, or beaten, and still give vent to their anger by tightening the hold which they got at first. There is nothing indeed which will loosen a staunch bull-dog, but that general means of truce to all canine hostilities, a copious effusion of cold water. This is a curious fact in the natural history of dogs, inasmuch

as it shows that there is some physiological relation between the fury of dogs when excited to a very high pitch and the dreadful malady of canine madness, or hydrophobia; for whether as displayed in the dog itself, or in those dreadful instances of human suffering which follow from the bite of a rabid animal, there is an indescribable horror of water, altogether independent of the difficulty of swallowing that or any other liquid. So remarkable is this that the very sight of water appears to shake the whole nervous system to pieces, and from the terrific expression of it the feeling itself must be dreadful.

If a bull-dog attempts to attack or to bite any part of an animal except the head or throat, he is considered as being of inferior breed, and not wholly a murderer in his disposition, which is the character that procures him the highest estimation among that description of persons who keep bull-dogs. Those dogs are not now so numerous, or held in such high estimation, as they were in former times; and we believe we may say, that the keeping of them for what is called "sport" is confined to the very lowest and least reputable characters, whatever may be their nominal rank in society. Formerly, however, the savage practice of baiting bulls publicly was very much in vogue; and it was then held as having no mean place among what were called "manly sports" in England, though they were in truth "beastly cruelties." In the reign of Henry II. bull-baiting was an amusement of the London populace. Nay, much more recently, Queen Mary entertained the French ambassadors two successive days with an exhibition of this kind in the year 1559. Queen Elizabeth, her sister, repeated it to the ambassadors from Denmark in 1586, and, what is more extraordinary, the former was herself among the spectators. Paul Hentzner, still later, describes the cruel diversion of the English people, to whom the baiting of bulls, bears, and badgers was familiar; and there is even reason to believe that the horse was sometimes publicly worried to death, to glut their savage appetites for a brutal spectacle. On all these and similar occasions, such as when a bull, jointly pursued by the dogs and their masters, was hunted down or bruised to death with clubs, the minstrels, a miscreant crew, claimed the slaughtered animal as a perquisite. It is long since the worrying of bulls in London was prohibited, but the practice was widely extended; and the ring to which the bull was chained for the certainty of undergoing aggravated torment, is still extant in many towns and villages, where they are sometimes converted to use. It is in all probability, from the "bull ring" being the regular place of rendezvous for all sorts of savage sports, and not from the form of the enclosure used on such occasions, that the place where, for a time, the bull-dogs of the human race continued the "sport," by mauling one another, first obtained the name of the ring. These things have fortunately, however, had their day; and future ages will be astonished that, not many years ago, the practice of bull-baiting was defended in the British parliament as a means of improving the spirit of the people.

**THE MASTIFF.** This is one of the most powerful of the whole race of dogs, and, for the purposes to which he is applied, one of the most serviceable. His aspect is not quite so expressive of unmingled ferocity as that of the bull-dog; and when he is not aroused, there is a considerable expression of repose, and even of dignity, about him. Those who profess to be

most deeply learned in the pedigree and progressive history of dogs describe the mastiff as an original English breed; and we believe it is true that mastiffs were formerly much more numerous in England than they are at present, and that in those earlier times the breed was less contaminated by crosses, and the animals altogether of superior quality. It is understood that English mastiffs, as well as English blood-hounds, were known and esteemed in the time of the Romans, though it is perhaps not very easy to say what varieties were then meant, or how far they agree with or differ from those of the present time. There are certainly not so many mastiffs in the continental countries as there are in Britain; the watch-dogs there usually partake more of the character of the wolf-dog, or of the French martier.

As it is only in the character of a watcher that the mastiff is valuable, it is easy to see why the use of him in this country should have fallen off. When police regulations were much less attended to, the population thinly scattered, and the moral habits of the people, in matters of *meum* and *tuum*, rather lower, the services of the watch-dog were in general requisition; and both the strength and ferocity of the dog, and the loud alarm which he is capable of giving, were of great service, the one to check the depredator, and the other to arouse the inmates of the house. Though this dog, like the bull-dog, always attacks in front, and aims his attack in a deadly manner, yet he does not, like that animal, attack without warning given. The bull-dog, as a watcher, ought never to be kept in any other way than chained, because he bites without previously giving mouth, bites indiscriminately or capriciously and, even when he is successful in seizing one of a party, he gives no alarm to afford security against the others. The mastiff, by giving an alarm, always warns on the one hand, and calls attention on the other; and a thorough-bred mastiff, if not kept on the chain, will not bite unless something under his charge is attempted to be taken hold of by some one with whose person he is not familiar. If chained, he is far more ferocious, and flies indiscriminately at all strangers that come within his reach, while, if the animal is powerful, and the chain at all fragile, his violence is apt to tear it asunder. It seems, indeed, that this chaining up completely destroys the more valuable qualities of the mastiff, and inflames all his bad ones; for, when he is allowed his freedom, he does not show much ferocity, unless the circumstances are such that, according to his training, there is cause and justification for his rage. In extensive yards and manufactories, where a mastiff is duly fed and watered, and left to his range, it is rather pleasant to observe with what dignity, and in how business-like a manner, he does his duty. All the people employed about the work, and also those who come at the regular hours, and in the regular way of business, are quite unnoticed by him; but, if any one is prowling about, or comes when the people about the place are all at rest, the mastiff instantly has an eye upon him, watches his motions with the most scrupulous attention, barks on the least offer of interference with anything under his charge, and attacks whenever interference is actually made. There are many instances, too, in which this dog has taken prisoners; and kept them, without doing them any injury, compelling them to stand fast, without advancing or retreating, under dread of the severest penalty. Nor

have there been wanting instances in which a dog of this kind has thrown a refractory intruder on his back, and held him there uninjured, though in no very enviable situation, till the return of day, and the arrival of those for whom he kept watch. It is also worth while to observe a really good dog of this kind going his rounds over extensive premises. One would almost imagine that he has got a complete catalogue of the property, together with plans of all the holes and hiding places, for he leaves not a suspicious spot unexamined; and he does it all peaceably, if all is right, and then returns good humouredly to his watch-house.

The mastiff has no trick or play about him, very little disposition to hunt any animal, and it does not appear that his sense of smelling is at all acute. His character is too dignified, and his deportment too grave, for these matters, but still he has a wonderful aptitude in acquiring a knowledge of those duties for the performance of which his nature more immediately fits him; and when he has acquired this knowledge, no servant can be more faithful, or, generally speaking, more quiet and orderly in the performance of them. As we have said, the period of especial necessity for the mastiff, except in particular situations, has gone by, but still there is something respectable in the memory of this animal, which makes one almost regret that the pure race have been, in many cases where watch-dogs are still used, supplanted by mongrels. There is one circumstance in the character of modern depredators, as compared with those of former times, which has rendered watch-dogs of much less value than they were then. The depredators of the olden time came by force, and therefore they could be met and repelled by force; but the modern ones proceed by craft, and the art of silencing a watch-dog is, we believe, part of the regular system of education among our midnight plunderers. In consequence of this, the dog merely serves to alarm the timid, while against those who are bent upon mischief he is of little or no use.

**THE BAN-DOG.** This appears to have been the old name of all watch-dogs in England which were not of the true mastiff breed. The name is evidently a corruption of "*baying-dog*," that is, a dog very prone to give tongue—one whose bark was more formidable than his bite. Such dogs were of course mongrels, and differed in their dispositions and qualities according as they were more allied to one race or to another. Of such dogs no general description can be given, nor is any necessary.

**THE CUBAN MASTIFF.** This breed is very common in the island from which the trivial name is derived, and there it answers the purposes both of a mastiff and a bull-dog, being used for watching, and also in bull fights. These dogs are represented as being very faithful, and at the same time very courageous and staunch; they are smaller in size, and somewhat less dignified in expression than the true mastiff, but they have the broad head, the produced upper lip, and the pendent ears. Their bodies are about a mean in size between the mastiff and the bull-dog, and they are rather more muscular than the first of these, and less so than the second. Their covering is very short and close, but, as is the case with all dogs in a state of complete domestication, their colours are very various.

There are many breeds of what may be called useless dogs belonging to the short-nosed division, of which it will be quite enough to mention a few of the

names; and, indeed, they may all be regarded as in some way or other varieties of the *pug-dog*, which is a cowardly little animal, and at the same time snappish, and not susceptible of much education, or much attachment even to those who make a pet of it.

Cuban Mastiff.

The enumeration which we have given includes at least as full a view of the leading varieties of the dog as is necessary for the purposes of general knowledge, that is, for those who are neither professional zoologists nor dog-fanciers, and, of course, the technical information which they require would be useless to the public. We shall, therefore, close this article by one or two remarks on the dreadful malady to which this faithful, and, in its own place, valuable race of animals, is sometimes subject, and which, in the bitterness of their own agony, they sometimes most unhappily impart to human beings. This is the malady usually designated as *canine madness*, from its affecting dogs more readily than any other animals; and it is also called *hydrophobia*, because a dread of water is usually, though not invariably, one of its symptoms. But neither of those names is exactly expressive of the nature and characters of this dreadful malady—a malady which is more terrible than any other casualty to which human nature is subject, and which, we may add, is generally or invariably communicated by dogs which are altogether useless to their keepers, and very often nuisances to every one else. The most usual symptoms of this malady are said to be dulness, loss of appetite, and, in particular, a departure from the animal's ordinary habits. If a stick, held out by a person with whom it is familiar, excites resentment, this is reputed an infallible criterion. But the dog still continues tractable, and the persons generally around it are the least in danger of attack. Its voice next becomes more of a continued howl, with the head elevated in the air; great anxiety appears; it labours under apparent suffering, and testifies the strongest impatience of controul. At length it eagerly hurries from the house to which it has always been attached—it bites every animal in the way—its pursuit is incessant of all except mankind, for they are more rarely the objects of injury; and, when worn out with wandering, it will sometimes return. If escaping intentional destruction, the dog seldom survives the fourth or fifth day, refusing all food, and dying raging mad. It is a lamentable fact, that a mortal malady, known by the name of hydrophobia, may be imparted

by the bite of a dog indisputably rabid; but this distemper does not invariably ensue; neither can it be correctly designated the dread of water, for some dogs lap that fluid readily, from the fever affecting them, though they are unable to swallow it. Instant excision of the wounded part is always considered prudent, where it may be safely performed; and of late, excessive bleeding, such as repeatedly deprives the patient of sense and motion, seems to have been practised with success. More recently, this and some other spasmodic diseases, which are generally found to be incurable by any of the ordinary modes of treatment, have been treated by inoculation with hydrocyanic (prussic) acid, wourali poison, and some other of those substances or preparations which are most immediately fatal to life. The object is to produce a complete suspension of all the functions of the system—a sort of temporary death, as it were; and then, if the patient can be resuscitated from this temporary death, the disease is found to have left him. This is a desperate means of cure, and may be expected to be in most cases as bad as the disease, in so far as the life of the patient is concerned; but, even if the application is followed by death, the quantity of suffering is very much abridged by it; and as there is a ray of hope, though a very faint one, the application is justifiable in extreme cases, but in such cases only. The rationale of the application appears to be this:—All spasmodic diseases, or diseases which affect the functions of life rather than any part of the organisation, completely cease when life is extinct, without continuing in the form of putridity in the dead subject, as is the case with diseases of the organisation. Hence, if we can cause the life utterly and completely to cease, even for an instant, the disease is destroyed; and as the life is intimately connected with the organisation, while the disease is not, there is, as it were, a smouldering ember of the one, which lingers for a little after the other is gone; and if the proper stimuli can be applied to the organisation, so as to make it re-act and the life to return, it returns altogether freed from the disease. How long this power of re-action may continue, is a very nice and delicate; and must vary with the circumstances of each particular case. But the subject is one of the deepest interest, and eminently deserving of the most minute, careful, and scientific investigation by those whose profession it is to watch over the health of themselves and their fellow-men. It is of much too abstruse and delicate a nature for popular discussion, and even in the medical world it is new, and safe only in the hands of the most cautious and skilful.

DOG POISON is the *Aethusa cynapium* or fool's parsley of Linnæus, a common British weed.

DOG'S-BANE is the *Apocynum androsaëfolium* of Linnæus; a flower-border plant of easy culture. The *Aconitum nictotinum* of Reichenbach is also called dog's-bane.

DOG'S-TAIL GRASS is the *Cynosurus cristatus* of botanists, and a valuable agricultural plant, as forming a chief part of the herbage on upland meadows and pastures. It is the *Hendon Bent*, so much prized in the London hay-markets. This grass is always chosen as part of the mixture of seeds for laying down permanent meadows or pasture land.

DOG'S-TOOTH VIOLET is the *Erythronium dens Canis* of Linnæus, a beautiful tuberous-rooted perennial herb, belonging to *Hexandria Monogynia*,

and to the natural order *Liliaceæ*. See ERYTHRONIUM.

DOG-WOOD is the *Cornus Suecica* of Linnæus.

DOLICHOPIDÆ. A family of dipterous insects belonging to the section *Tanystoma* of Latreille, comprising an extensive group of flies, having the body generally compressed, the head triangular and slightly produced into a muzzle in front, the abdomen curved downwards at the extremity, and the legs very long and furnished with numerous small spines; the antennæ are short and composed of three joints with an articulated bristle; the wings have only one or two discoidal cells, the nervures nearly resembling those of the common fly.

These insects, which are generally found in damp situations, seldom exceed in size the domestic fly, have the body highly ornamented with green and other metallic tints, and in many species various remarkable sexual and other peculiarities are to be observed which are not found in other dipterous insects. They reside upon the leaves of plants, where their agility and brilliant colours render them conspicuous; others are to be seen running along the margins of streams; they seldom are observed extracting the honey from flowers, but rather sip the dew from the leaves. They walk sideways with as much facility as in a straight line. M. Macquart has observed one of them which had seized the larva of one of the small cicadæ, the body of which was half hidden within the large lips between which it was introduced, the sucker of the mouth being at the same time employed in extracting its fluids. According to De Geer, the larva of one of the species resides under ground, where the pupa is transformed.

There are numerous generic and subgeneric divisions established in this group, founded upon structural characters, but which it would be tedious in a work like the present to detail. The typical genus is *Dolichopus* of Fabricius, of which there are thirty British species, including the *Musca nobilitatis* of Linnæus. The student should consult Mr. Haliday's Memoir, published in the Zoological Journal, No. 49, and that published in a late number of the German periodical, the *Isis*, in which numerous new species are described.

DOLICHOS (Linnæus) is a genus of annual and perennial climbing plants, found in every quarter of the world. Class and order *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx bracteate, bell-shaped, five-toothed, two upper teeth united; standard spreading, furrowed at the base; keel angular, incurved, and obtuse; style flattened, bearded above; pod compressed with contractions between the seed-cells. These plants are easy of culture, growing in any kind of light soil, and may be propagated by cuttings: the annual sorts by seeds. A great many new genera have been separated from this.

DOLOMEDES (Latreille). A genus of erratic spiders, having the eyes arranged in a quadrilateral position, but somewhat broader than long, and in three lines, the anterior of which has four eyes, and the two posterior lines two eyes each, the hinder pair being slightly elevated on footstalks; the second pair of legs is as long as the first; the lip is short and square. These spiders, do not construct a web, but chase and run after their prey in the same manner as the *Saltici*, a very active group, the species of which are constantly to be observed on walls, creeping very

cautiously along, and jumping from considerable distances upon flies and other insects. The *Dolomedes*, however, at the period of laying their eggs, form a little web upon the plants, within which a cocoon-like mass may be observed which contains the eggs. These they guard with great caution, as well as the young as soon as they are hatched. Moreover, when disturbed, they run off with their egg bag. The type of the genus is the handsome *Aranea marginata*, found on the margins of streams, and figured in Kirby and Spence's Introduction to Entomology, vol. ii. pl. 5, fig. 4.

**DOMBEYA** (Cavanilles). A genus of ornamental trees, indigenous to the islands of Bourbon and Mauritius. Linnæan class and order, *Monadelphica Dodecandria*, and natural order *Byttneriaceæ*. Generic character: calyx five-parted; stamens numerous, growing out of the base of the tube. Ligulæ long, and linear between every three stamens; style filiform, five-cleft at top, stigmas reflexed; capsules five, one or many-seeded, two-valved, united; seeds oblong. These plants are grown in loam and moor-earth, and are propagated by cuttings in sand in a moist heat.

**DONACIA** (Fabricius). A genus of coleopterous insects belonging to the section *Tetramera* and family *Crioceridæ*, having the body oblong and depressed, the antennæ moderately long and of equal thickness throughout, the posterior thighs often thickened and toothed beneath, the jaws robust with two or three acute terminal teeth, and the terminal joint of the tarsi received between the lobes of the third joint. These insects, of which there are upwards of twenty British species, are of elegant form, and generally ornamented with brilliant colours of a metallic kind. They are also furnished with a silky down on the under surface of the body, which is of service to them by preventing them from sinking when they fall into the water, upon the plants growing in which they reside often in considerable numbers. In the twelfth number of the Magazine of Natural History is contained an account of the discovery of the egg-shaped transparent brown cases of one of the species containing the perfect beetle, on the stems of *Arundo phragmites*, close to the root, and immersed in the water or mud. It is not, however, stated at what period of the insect's existence these cases (which are described as the winter quarters of the *Donacia*) were constructed. It might indeed be inferred from the perfect beetles being found in them that they were constructed by the beetles for their abode. But that they were intended neither for permanent nor occasional abodes is evident from the external habits of the insects. They might perhaps indeed be supposed to be constructed by the beetles for their winter abodes, but, as Messrs. Kirby and Spence observe, "it does not appear that any perfect insect has the faculty of fabricating for itself a winter abode similar to those formed of silk, &c. by some larvæ. Schmid indeed has mentioned finding *Rhagium mordax* and *Inquisitor* (beetles nearly related to *Donacia*) in such abodes, constructed, as he thought, of the inner bark of trees; but these, Illiger has suggested, were more probably the deserted dwellings of lepidopterous larvæ, of which the beetles in question had taken possession." The circumstance of the cases of the *Donacia* being found at the root of the plants immersed in the water is sufficient to prove that they were not formed by the beetle, since it cannot be

supposed that an insect living above the surface of the water and constantly on the wing would select a spot for its winter abode beneath the surface of the water. It only therefore remains to regard these cases as the production of the larvæ, within which the perfect beetles are transformed at an early period, so as to take advantage of the first fine days of spring; and indeed Messrs. Kirby and Spence expressly state "that amongst the larvæ which enclose themselves in silken cocoons are those of the brilliant beetles frequenting aquatic plants, constituting the genus *Donacia* (Fabricius), and that the case of *D. fasciata* is fastened by one side to the roots or surculi of *Typha latifolia*;" and the following observations from the same authors will perhaps be regarded as sufficient authority for our regarding the larvæ as the architects of the cells, and at the same time for enabling us to account for the discovery of the perfect beetles in the winter:—"Insects of the beetle tribe, especially such as undergo their metamorphosis under ground, in the trunks of trees, &c., are often a considerable time after quitting the puparium before their organs acquire the requisite hardness to enable them to make their way to the surface; thus the newly disclosed imago of *Cetonia aurata* remains a fortnight under the earth; and that of *Lucanus cervus*, according to Roesil, not less than three weeks."

One of the handsomest, and, at the same time, most abundant species, is the *D. Proteus*, so named from the endless variety of colours which it assumes, varying from a rich red to copper, purple, blue, green, bronze, &c. It is to be met with upon plants in ditches in almost every situation, and is about one third of an inch long. There are about twenty other British species.

**DONAX** is the specific name of the arundo-donax of Withering, a reed common in the south of Europe.

**DORCUS** (Macleay). A genus of stag-beetles (*Lucanidæ*), distinguished by having the jaws but of moderate size, the antennæ terminated by a four-jointed sub-perfoliated club, the head very broad, and the upper lip distinct. The only British species is the small stag-beetle (*Lucanus parallelopedus*, Linnæus), which is about an inch long, a little more or less, and of a black colour. It is found in decaying trees in various parts of the country.

**DORIPPE** (Fabricius). A curious genus of crustaceous animals belonging to the *Brachyeros decapods*, or crabs, and to the section *Notopoda* of Latreille, so named in consequence of two or four of the posterior legs being rudimental and dorsal. The shell is of an ovoid form, truncate behind, the claws are very small, and the four hind legs short and slender. There are three Mediterranean species of crabs belonging to this genus, of which the *Cancer lanatus* of Linnæus is the type.

**DORITIS**, Fabricius; (*PARNAËSIUS*, Latreille). A handsome genus of butterflies (*Lepidoptera diurna*), differing from the true genus *Papilio*, *Machaon*, &c., by having the palpi evident, in front of the head, and composed of three distinct joints. The club of the antennæ is short. The females have a kind of corneous pouch at the extremity of the abdomen. The caterpillars, like those of the true papilionæ, have the neck furnished with a retractile fleshy appendage, but they differ from the majority of butterfly-caterpillars in constructing a cocoon, in which they are transformed into chrysalides. The species, of which there are but few in number, inhabit the mountainous dis-

tricts of Europe, being found upon the Alps, &c. The type is the *Papilio Apollo* of Linnæus, which, like most of the species, is of a white colour, with four eye-like spots with red and black circles.

**DORONICUM** (Linnæus). A genus of herbs, chiefly European, belonging to *Syngnæstia superflua*, and to the natural order *Compositæ*. These plants grow freely in any garden soil, and are easily increased by division: they flower early in the spring. Leopard's Bane is their English name.

**DORSTENIA** (Linnæus). A genus of plants, remarkable for their manner of flowering. Linnæan class and order *Tetrandria Monogynia*, and natural order *Urticeæ*. Generic character: receptacle fleshy, somewhat concave, quadrangular or roundish, bearing both male and female flowers. Perianth none; stamens mixed with styles; anthers two-celled; styles laterally bifid; seeds naked, in cavities of receptacle. This plant is cultivated in the stove more as a vegetable curiosity than for its beauty, for neither its flower or foliage can be called handsome. It is easily increased by dividing the root or by seed.

**DORTHEZIA** (Bosc). A genus of small but curious insects, nearly allied to the *Coccidæ*, which see. The species are found upon plants, the males are adorned with a long and pencil-like tail, and the females are covered with waxen scales of various forms, which give them a very remarkable appearance. They are of small size.

**DORY, DORÉE, or "JOHN DORY,"**—*Zeus faber*. A celebrated species of fish belonging to the spinous finned order, the mackerel family, and the genus *Zeus*; but because it has been in all ages a fish of some celebrity, we have deemed it necessary to give a short account of it under its common English name. "John Dory," its usual name among the fishermen, has no connexion with the name John any more than *anchovy* has with the name Anne, though every one must be aware of the punning allusion to eating dory with anchovy sauce, as being "the legitimate marriage of John Dory and Anne Chovy."

This fish was known to the Greeks and to the Romans, and the former have left evidence of the estimation in which they held it, in having named it after Zeus or Jupiter, the captain-general of the gods. Nor are we without evidence of the esteem in which this fish was held by the monastic epicures of the middle ages, for it was one of those fishes which they coupled, by means of legendary fables, with the sacred name of the founder of Christianity. Whenever we find any fish or other animal thus connected, we may always make certain that such fish or animal is a *bonne bouche*, for the very same reason that the term *Lachrymæ Christi* has been applied to the most luscious production of the vine. Thus, though those fables are, to say the best of them, specially absurd in their original application, they all afford some useful lesson in the way of good eating, and there is no reason why we should throw away this because it is connected with an absurd fable. The ocellated spots, which are so conspicuous in the dory, are like those less conspicuous ones on the haddock, the marks left by the finger and thumb of St. Peter, as he held the fish in the one hand, and took the tribute money out of its mouth with the other. It does not appear that the inventors of this fable, who no doubt had a view to the ample supply of these half-canonised fishes, had much regard to the apostle's character for cleanliness; for, if they had reflected a little, they must have per-

ceived how shockingly dirty the thumb and finger must have been in order to stain fishes with indelible black spots down to perhaps the thousandth generation, and as much longer as this species may tenant the sea. As the one piece of tribute money could not well be taken out of the mouths of two fishes, neither of which is, we believe, to be found in any of the salt lakes of Judea, which are the only seas alluded to in the Gospels, therefore the dory gets another chance of having received these spots as a mark of such saintship as credulity might suppose to belong to a fish. It is said that St. Christopher, while wading through an arm of the sea with our Saviour on his back, caught a dory, and impressed the spots with his thumb and finger, which is of course as ridiculous as the former story, and meant to answer exactly the same purpose. Our common name John Dory is clearly nothing more than a corrupt pronunciation of the French term for the colour of the lighter parts of the fish, which is yellow with metallic reflections; when the fish is alive, and therefore very properly styled *jaune dorée*, or gold and yellow.

We shall avail ourselves of Mr. Yarrell's very excellent and accurate description of this fish in his work on the history of British fishes; and we do this the more readily, that it gives us an opportunity of saying that this work is one of the few which tend to confer the highest honour upon the author, and render the greatest assistance to the public in the real knowledge of the subject. "The body of the dory," says Mr. Yarrell, "is oval, very much compressed; the head large; the mouth capable of great protrusion, so much so, that from the point of the lower jaw, when extended, to the posterior angle of the operculum is as long as from that angle to the base of the caudal rays. The length of the head when the mouth is not projected is nearly as long as the body is in depth. The mouth large; the teeth small and numerous, placed in a single row in each jaw, and curving inwards; the eyes large, situated laterally and high up on the head; irides yellow; a spine behind and over each orbit, about half way between the eye and the first ray of the spinous portion of the dorsal fin; the spines of the first dorsal fin very long, the longest half as long as the body is deep; the membrane between the spines ending in a filament three times as long as the rays. The base of the second dorsal fin about as long as that of the first; the rays flexible, and only half as high as those of the first; the pectoral fin small and short, ending on a line with the anterior edge of the dark spot on the side; the ventrals very long and slender; arising in advance of the pectorals, the rays reaching as far back as the first flexible ray of the anal; the first spinous ray of the anal fin is on a line with the posterior edge of the dark spot, and with the sixth spinous ray of the dorsal; the flexible portion commences and ends nearly on the same planes as the flexible dorsal. The tail is narrow, long, and slender; the lateral line, advancing at first straight, afterwards rises in an elevated arch over the dark spot, which is placed at about the diameter of its own breadth behind the posterior angle of the operculum. A row of spiny scales pointing backwards are ranged along the base of the dorsal and anal fins on both sides.

"The prevailing colour of the body is an olive brown, tinged with yellow, and reflecting in different lights, blue, gold, and white; when the living fish, just taken from the net, is held in the hand, varying

tints of these different colours pass in rapid succession over the surface of the body. The membranes of the flexible portions of the fins are light brown; those of the spinous portions are much darker.

"A large portion of the dorées supplied to the London fish market is brought by land carriage from Plymouth and some other parts of the Devonshire coast. Being a ground fish, they are little or none the worse for keeping till the second or third day. Montagu, disliking the toughness of a fresh-caught dory, says they are most palatable after keeping two days. Fish for the supply of the London market was not brought by land carriage until the year 1761. Steam boats seem likely to effect another change. In the summer of 1834, a cargo of salmon from Scotland was deposited in the London market within forty hours."

The dory is not a very common fish upon the British shores; and its appearance is apparently capricious as well as local. It belongs to warmer seas, and therefore it is never found on the north and north east coasts of the island, and very rarely on the east, and not, we believe, further to the northward than the coast of Norfolk, upon which it may be considered more in the light of a stray than of a regular visitant. On the south-west coast it is much more common, being sometimes abundant on the shores of Cornwall and Devon, though rarely further to the eastward. In Ireland it comes round both ends of the island, as far as Waterford on the south, and the coast of Antrim on the north. From this we may conclude that it should be found all along the west coast of that island. There are, however, some difficulties attending both the places and seasons of resort of those wandering fishes to which the dory belongs. Though classed with the mackerel family, the greater number of which are surface fishes, and migratory in shoals with considerable regularity of season, the dory is described by Mr. Yarrell, and all those who have the best opportunities of ascertaining its habits, as being "a ground fish." From the structure of the fish, the habits of the rest of the family, and the situations in which this particular member of it is found, we should not be inclined to give it so deep a situation in the waters as that of an absolute ground fish; though it certainly does inhabit lower down than most of the others. According to Mr. Couch, it follows the shoals of pilchards, and also feeds on the cuttle, which is not, any more than the pilchard, an inhabitant of the sea bottom; and the same authority, and we believe he will not be questioned as to the accuracy of his facts, mentions that the dory is 'seen floating along with the current, which again is not the habit of a ground fish. The produced filaments, the singular shape, and the means of entanglement which the whole external structure of the dory presents, clearly point it out as a fish which has not much command of itself in the water, and therefore as one which must be to a very great extent at the mercy of every current in which it happens to be taken. But at the same time the structure of the fish corroborates the facts mentioned by Mr. Couch, as to the floating of this fish being nearer the surface of the water than the bottom. We are not acquainted with any habitual ground fish with a compressed body, at least with the compressed body so placed as that its motion in the water is, with the most extensive dimension, vertical. All the flat fish, which are ascertained to be bottom ones, have the breadth of the body turned the other

way, and there is not one of them furnished with fins bearing the least analogy to those of the dory. Their organs of motion are all constructed for acting most effectively either upwards or downwards, and they are in general short, and continuous round the extremities in the flattened direction. The organs of the dory are, on the other hand, chiefly constructed for lateral motion, without any powers of ascent and descent so strikingly indicated as we find them in the flat fishes. If, therefore, the authorities are correct in stating that the dory is a ground fish, it forms a curious anomaly to the generality of fishes which have that habit, and may be regarded as being as great a curiosity in natural history as it is in the annals of superstition and gastronomy. It is well known that Quin, who was equally remarkable for his comic powers in the theatre, and his epicurean propensities at the table, contributed mainly to bring this fish into that public notice which it has since enjoyed; and as the circumstances of this case are calculated to throw some light both on the fish and the man, we shall venture to give an anecdote not, we believe, generally known, which Mr. Yarrell quotes from a manuscript of the amiable and indefatigable Colonel Montagu. "It is now," says the colonel, "about sixty years (at present, 1835, it is nearer eighty) since the celebrated Mr. Quin, of epicurean notoriety, first discovered the real merit of the dorée; and, we believe, from him originated the familiar, and we may say national, epithet of 'John Dory,' as a special mark of his esteem for this fish; a name by which it is usually known in some parts, especially at Bath, where Quin's celebrity as the prince of epicures was well known, and where his palate finished its voluptuous career. Notwithstanding the numerous anecdotes recorded of this gentleman, as famous for his love of good living as for his excellence as a comedian, and who shone equally as a *bon vivant* as in the character of Falstaff, we may be allowed to record one more in honour of both the person who brought the dorée into such high estimation and of the fish itself. An ancestor of ours, a Mr. Hedges, was an intimate friend of Quin, and was induced by him to take a journey from Bath to Plymouth, on purpose to eat 'John Dory' in the highest perfection, not only from procuring it fresh, but with the additional advantage of having it boiled in sea water, a matter of very great importance to the palate of Quin. As this journey was purposely taken to feast on fish, their stay at Plymouth was not intended to exceed a week, by which time they expected to have their skins full of dorée; but that no opportunity might be lost, Quin left strict charge with the host at Ivybridge to procure some of the finest dorée he could get for his dinner on his return, fixing the day. Whether our celebrated epicure was disappointed in his expectations at Plymouth is not recollected; but that he might have the provided fish at Ivybridge in the highest perfection, and remarking that the place was too remote from the coast to obtain sea water for dressing the dorées anticipated, he ordered a cask of sea water to be tied behind his carriage. Unfortunately the weather had been stormy, and no fish of note could be procured. Every apology was made by the host, who assured him that an excellent dinner was provided, which, he had no doubt, would be to his taste, but no fish. The disappointment, however, was too great to be borne with patience; after having made a water-cart of his carriage, and the appetite having been set for 'John

Dory' boiled in sea water, no excuse, no apology would satisfy Quin, and he declared he would not eat in his house, but, like a ship in distress, threw his water cask overboard, and pursued his journey not a little sulky, till some fortunate stroke of wit or some palatable viand roused him to good humour. This western tour of Quin's did not appear to have given him much satisfaction, as may readily be imagined by his reply to a friend on his return to Bath. Being asked if he did not think Devonshire a sweet county, 'Sir,' said Quin, 'I found nothing sweet in Devonshire but the vinegar.' Such is a specimen of Quin's *Ichthyomania*, as left on record by Colonel Montagu, and with it we shall close our short notice of the dory, leaving the reader to judge whether the history of the fish or the actor be the more curious subject of the two.

**DORYANTHES** (Correa de Serra). A large herbaceous plant, a native of New South Wales. Class and order: *Hexandria Monogynia*, and natural order *Amoryllideæ*. Generic character: flowers on a bracteated fascicle; corolla funnel-shaped, six-cleft; stamens inserted into the base of the segments; filaments awl-shaped; anthers like fingers, erect, four-sided; style three-furrowed; stigma three-sided; capsule three-celled, three-valved; seeds disposed in pairs. This gigantic herb bears cream-coloured flowers, and does very well in a green-house. It sometimes produces suckers, by which it may be increased.

**DORYLUS** (Fabricius). A genus of singular hymenopterous insects, of which the males only have hitherto been observed, belonging to the family of *Mutillidæ*. The body is long, and the abdomen knotted at the base; the antennæ are short and slender, and inserted near the mouth, the various parts of which are very small; the legs are very short, with the thighs flattened. There are at least two species inhabiting India and the Cape of Good Hope. The writer of this account has been informed by the celebrated African traveller, W. Burchell, Esq., that their habits are nocturnal. The genus is represented in South America by that of *Labidus*, which differs chiefly in the structure of the mouth, and smaller size. The type of the *Dorylus* is the *Mutilla helvola* of Linnæus.

**DOVE'S FOOT** is the *Geranium molle* of Linnæus, a common British plant.

**DRABA** (Linnæus). An extensive genus of small herbaceous annuals, biennials, and perennials, natives of the coldest and most rocky regions of Asia, Europe, and America. They are tetradynamous, and belong to *Cruciferae*. Several species of this family are early flowerers, which gain them admittance into the flower-gardens, and are particularly useful for rock-work.

**DRACÆNA** (Linnæus). Tropical trees and shrubs of a very unusual colour; hence the name, as their juice is said to furnish or resemble the drug called dragon's blood. The flowers are hexandrious, and the plant belongs to the order *Asphodeleæ*. Generic character: corolla spreading, regular, six-parted, deciduous. Stamens inserted in the base of the corolla; filaments membranous at the base, thick in the middle, and awl-shaped at the apex. Style rather angular; stigma three-cleft; berry six-furrowed, three-celled, cells mostly one-seeded. These plants give variety to the stove collection by reason of the deep purple hue of the foliage. "Large cuttings root

freely by being stuck in the bark-bed in a brisk heat."

—Sweet.

**DRACOCEPHALUM** (Linnæus). A genus of odoriferous annual and perennial herbs, mostly found in the north of Asia, Europe, and America. Class and order, *Didymia Gymnosperma*, and natural order *Labiateæ*. The best known and most generally cultivated species of this genus is the *D. Canariense*, the balm of Gilead, met with in every greenhouse, not because of its beauty either of flower or foliage, but entirely for its pleasant and powerful scent. It may be propagated either by cuttings, seeds, or division of the roots.

**DRACONTIUM** (Linnæus). A genus of curious creeping plants, natives of India, belonging to the seventh class of Linnæus, and to the natural order *Aroideæ*. Generic character: spathe of one leaf; spadix cylindrical, to which the flowers are attached; perianthe cut into five or six petal-like scales; stamens inserted into the bases of the scales; filaments linear; anthers oblong, two-celled, opening by a pore at the top; style elongated, three-sided; berry three-celled, three-seeded. These are plants of no beauty, but curious in form. They grow in any light soil, and are increased by division.

**DRACOPHYLLUM** (R. Brown). A genus of handsome shrubs, natives of New Holland. Linnæan class and order, *Pentandria Monogynia*, and natural order *Epacrideæ*. Generic character: calyx five-parted; corolla tubular; limb beardless, five-cleft; stamens below the germen, or fixed to the base of the corolla; anthers fixed by the back; style simple; stigma three-lobed; five scales below the germen; capsule with a central placenta. These plants grow well in the common compost of moor-earth, sand and loam, and are propagated by cuttings.

**DRAGON-FLY**—Adder-bolt, or Horse-stinger. The ordinary names by which numerous large species of neuropterous insects, composing the families *Libellulidæ* and *Agriionidæ*, are distinguished. Wherefore such names as these should have been bestowed upon the most harmless of insects we know not; by the French, the superior gallantry of whom is exhibited even in the naming of an insect, they are termed *Demoiselles*, from their elegant form and the delicacy of their wings, which are transparent as gauze, often ornamented with coloured spots, and exhibit, when viewed in different lights, all the iridescent tints of the rainbow.

The structural characters of this group of insects will of course be given under the systematic name, we therefore proceed to their natural history.

Nothing can be more beautiful than to watch these brilliant insects on a fine summer's day skimming over some standing water, and darting backwards and forwards. The object of this continual flight is the discovery and capture of small flies and other insects, which constitute their food. Like the swallows, which are their analogues, they have a mouth capable of much distension, and the long abdomen acting as a rudder enables them to effect the most perfect movements in the air, so that an insect when observed has but little chance of escape. Flies, moths, and even butterflies are seized, and the *Libellula* may often be seen flying about with a large insect in its mouth, more than equal in size to its own head. It is owing to the numbers of insects frequenting such situations, as well as to the circumstance that the *Libellula* are produced from aquatic larvæ, that they are so

commonly seen about water. Often two of these insects may be observed flying together in a line, the neck of the hinder one, which is the female, being held by the extremity of the tail of the one in front, or the male.

Shortly after this has been seen, in walking on the banks of water, a rustling sound may be heard amongst the aquatic plants growing thickly together, and which is soon discovered to be caused by the wings of the female touching the stems of these plants whilst in the act of depositing her eggs on the water. During this act the tail is beat upon the surface of the water with rapid succession, until the eggs form a mass somewhat like a bunch of grapes.

The larvæ are soon hatched, and the insect retains its aquatic habits until the moment when it assumes the winged state. So long as they remain in the water, they change their form but slightly, but retain nearly that which they exhibit at their first exclusion from the egg. Old Izaak Walton tells us a marvellous story about a green caterpillar or worm, as big as a peascod, "which I have seen, and may therefore affirm it to be true," found upon a privet hedge, and which was kept in a box, and fed with privet, "but by some neglect in the keeper of it, it then died, and did not turn to a fly; but, if it had lived, it had doubtless turned to one of those flies that some call flies of prey, which those that walk by the rivers may in summer see fasten on smaller flies, and I think make them their food." This green caterpillar was, however, doubtless that of the privet hawk moth (*Sphinx ligustre*); and as this fine moth is but seldom seen on the wing, it is not perhaps surprising that the old fisherman should have supposed that the large day-feeding caterpillar should turn to the comparatively large day-flying dragon-fly.

The larvæ of the dragon-flies have the body comparatively short and thick compared to that of the perfect insect; they are provided with six moderately long scaly legs. They shed their skin, and on becoming pupæ they are equally active as before, and have four small scaly pieces, which are the cases in which the large future wings are concealed. In their aquatic state these insects have a remarkable apparatus attached to the head, enabling them to seize their prey, which consists of other aquatic insects. It is so admirably described by Messrs. Kirby and Spence, that we give their account, with some omissions, rather than attempt its description afresh:—"One of the most remarkable prehensile instruments, in which the art and skill of a Divine mechanic are singularly conspicuous, and which appears to be without a parallel in the insect world, may be seen in the *under lip* of the various species of dragon fly. In other larvæ this part is usually small and inconspicuous, and serves merely for retaining the food and assisting in its deglutition, but in these it is by far the largest organ of the mouth, which, when closed, it entirely conceals, and it not only retains, but actually seizes the animal's prey by means of a very singular pair of jaws with which it is furnished. Conceive your under lip (to have recourse, as Reaumur did, on another occasion, to such a comparison) to be horny instead of fleshy, and to be elongated perpendicularly downwards, so as to wrap over your chin, and extend to its bottom, that this elongation is then expanded into a triangular convex plate attached to it by a joint, so as to bend upwards again, and fold over the face as high as the nose, concealing not only the chin and

the first-mentioned elongation, but the mouth and part of the cheeks; conceive, moreover, that to the end of this last-mentioned plate are fixed two other convex ones so broad as to cover the whole nose and temples, that those can open at pleasure transversely, like a pair of jaws, so as to expose the nose and mouth, and that their inner edges, where they meet, are cut into numerous sharp teeth and spines, or armed with one or more long and sharp claws, you will then have as accurate an idea as my powers of description can give of the strange conformation of the under lip in the larvæ of the tribes of *Libellulina*, which conceals the mouth and face precisely as I have supposed a similar construction of your lip would do yours. You will probably admit that your own visage would present an appearance not very engaging while concealed by such a mask; but it would strike still more awe into the spectators, were they to see you first open the two upper jaw-like plates, which would project from your temples like the blinders of a horse; and next, having, by means of the joint at your chin, let down the whole apparatus\*, and uncovered your face, employ them in seizing any food that presented itself, and conveying it to your mouth. When the insects would make use of it, they unfold it like an arm, catch the prey at which they aim by means of the mandibuliform plates, and then partly re-fold it, so as to hold the prey to the mouth in a convenient position for the operation of the two pairs of jaws with which they are provided. This conformation so exactly resembles a mask, that, if entomologists ever went to masquerades, they could not more effectually relieve the insipidity of such amusements, and attract the attention of the *demoiselles*, than by appearing at the supper-table with a mask of this construction, and serving themselves by its assistance. It would be difficult, to be sure, by mechanism, to supply the place of the muscles with which the insect is amply provided, but Merlin, or his successor, has surmounted greater obstacles. You will admire the wisdom of this admirable contrivance, when you reflect that these larvæ are not fitted to pursue their prey with rapidity like most predaceous animals, but

A, the pupa with its mask extended. B, the same with the mask closed, and discharging a current of water.

that they steal upon them, as De Geer observes, as a cat does upon a bird, very slowly, and as if they counted their steps, and then, by a sudden evolution

\* Not only is the front piece let down as described by Messrs. Kirby and Spence, but the basal descending piece is subsequently capable of protrusion by a hinge at its base.

of this machine, take them, as it were, by surprise, when they think themselves safe. De Geer says it is very difficult for other insects to elude their attacks, and that he has even seen them devour very small fishes. As these animals are found in almost every ditch, you will doubtless lose no time in examining for yourself an instance of so singular a construction."

The formation of this organ varies slightly in the different species, but the same general structure is observable through the whole of them.

The observation of De Geer, quoted above, upon the motions of these larvæ and pupæ, arises in some respect from another remarkable peculiarity exhibited by them, consisting of an instrument which serves for progression, although more immediately connected with the office of respiration. These insects have, at the extremity of the body, an aperture serving for the entry of a certain quantity of water, which there undergoes a process by which the air contained in it is rendered serviceable for respiration. The orifice of this aperture is defended by five scaly pieces, forming a kind of tail, and which are opened or shut together at the will of the animal. When, therefore, a supply of water has been taken into the cavity, these external pieces are closed, and other internal organs brought into action, for the purpose of extracting the vital principle therefrom; and when this has been effected, the external pieces are suddenly thrown open, and the internal fluid discharged with violence, a sudden forward jerk being thereby given to the body of the insect.

These insects live in the water ten or eleven months preceding their final change, during which period they change their skins several times. From the middle of spring to the commencement of autumn, the *Libellula* arrive at their perfect state. The nymphs or pupæ, ready to become winged insects, are known readily by their larger size, and by the figure of their wing-covers, which become detached from each other. They now quit the water, and ascend the stems of any aquatic plant, so as to allow their outer covering to dry and become brittle. Some are ready to quit their old covering in the course of two or three hours; others are so much as an entire day before this takes place. After this

terminal abdominal segments still remaining in the pupa skin, serving to support the insect. After remaining some time in this position, it again raises its head and body, seizes the stem of the plant with its fore legs, and draws out the remainder of the abdomen. In this position it remains a considerable space of time, until its wings, which hang downwards (and which, at first, are not larger than the cases by which they were covered), acquire their full size and beautiful gauze-like appearance. At the end of a couple of hours the insect is able to support itself in the air on the wing.

There are numerous species of dragon-flies, of which many are natives of this country. Some of them, forming the modern restricted genus *Libellula*, are remarkable for the diversity of colour in the opposite sexes, the abdomen in the males being of a beautiful blue, and that of the female yellow. The largest species of the group found in England is the *Anax imperator*, a noble species, a solitary specimen of which we observed, during several weeks, hovering over the same little pond on Wimbledon Common, Surrey, during the present summer.

**DRILUS (Olivier).** A genus of coleopterous insects, belonging to the section *Pentamera*, sub-section *Serricornes*, and family *Lampyridæ*, having the antennæ remote at the base, the head not narrowed in front into a snout, and the eyes of ordinary size in both sexes. The females are, however, destitute of wings, and their antennæ are but slightly serrated, whereas those of the males are very strongly pectinated. The mandibles are slender and acute at the tips, with a tooth near the extremity.

The genus is composed of but a few small species, of which the males only, until very recently, were known. Naturalists were also ignorant of their metamorphoses. We are indebted to the Count Meilzinsky for the first account of the female, and the transformations of the genus, which, as well as the economy of the species, are very curious. The larva is about three quarters of an inch long, and is found in the interior of the shell of the common snail (*Helix nemoralis* of Linneus), upon the inhabitant of which it feeds. When full grown (about the month of September), it remains for some time in an inactive state, during which period it was regarded by M. Meilzinsky to be in the state of the pupa. The observations of M. Desmarest proved such not to be the case. The latter author also ascertained, that, having remained in this inactive state until the month of May, the larva is transformed into a real pupa, in which state it continues perfectly inactive, unless when touched, when a drop of yellowish fluid is exuded from the sides of the body. M. Meilzinsky, not being aware of the connection of this insect with the well-known *Drilus flavescens*, regarded it as a distinct genus, to which he gave the name of *Cochleoctonus vorax*, establishing the genus upon the peculiarities observable in the large and unwieldy females, which are destitute of wings and wing-covers, like the glow-worm, and which nothing but direct observation would induce any one to regard as the other sex of the small and pretty drilus. M. Desmarest, however, assisted by his pupils, succeeded in rearing the apterous females from M. Meilzinsky's pupæ, and not only observed the coupling of the *cochleoctonus* and *drilus*, but also found, within one of the snail shells, the exuvæ of the male *drilus*, and which were easily recognisable from the peculiar construction of

A, the dragon-fly making its exit from the pupa. B, the same drying its wings.

process has taken place, the pupa attaches itself to a twig by means of its legs. Internal movements are now perceived, and the skin splits down the back, the slit gradually increasing in size, until a sufficient orifice is made to allow the head and legs to be drawn out, the head being thrown backwards, and the

the strongly pectinated antennæ, the cases of which were distinctly observable.

**DRIMIA** (Jacquin). A genus of bulbous plants, introduced from the Cape of Good Hope. They belong to the class *Hexandria*, and to the natural order *Asphodelææ*. Generic character: corolla bell-shaped, six-cleft, segments revolute; stamens inserted into the base of the corolla; filaments as long as the corolla; anthers roundish; style protruding; stigma headed; capsule three-celled, many-seeded. Leaf-mould and loam mixed is the most suitable soil for these bulbs, which require no water when dormant, but they should be fresh potted before they begin to grow, to ensure their flowering, and propagated by offsets.

**DRIMYS** (Forster), is a tree introduced from the Straits of Magellan by Captain King. Class and order *Polyandria Tetragynia*, and natural order *Magnoliaceæ*. This tree yields the true *Winter bark*, a valuable medicine, and which would be a great acquisition if it could be cultivated in any of the British colonies.

**DROMIUS** (Bonelli). A genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabidæ*, and distinguished from *Demetrius*, with which it is united by the French authors, by its broader outline, shorter mandibles, simple fourth joint of the tarsi, and the greater length of the second joint of the antennæ. The species are of small size, and are found beneath the bark of trees, in sand and gravel pits, &c. They are very active, and often prettily ornamented. There are about fifteen British species, of which the synonyms are very confused. See the Second Part of the Transactions of the Entomological Society of London for a valuable paper upon the species of this genus, by Mr. Babington.

**DRONE**. A name ordinarily given to any moderately large and sluggish fly, but strictly belonging to the male of the hive bee. See **BEES**. Many dipterous insects, indeed, so much resemble bees, that it is difficult to convince the ordinary observer of nature that they are not stinging insects. The possession, however, of only a pair of wings, is sufficient to show their harmlessness so far as stinging is concerned. Moreover, even the true drone, although a four-winged hymenopterous insect, is destitute of any sting, that weapon of defence being given only to the females and abortive females, or neuters.

**DROPWORT** is the *Spiræa filipendula*, or Queen of the Meadow, a common British plant found on the banks of rivers, or on damp meadow ground. Three varieties of it are in flower gardens.

**DROSERACEÆ**, the Sundew family, a natural order of dicotyledonous plants, containing seven or eight genera, and between forty and fifty species. It is closely allied to *Violaceæ*, but differs in its circinate veneration, in having several styles, a minute embryo, and exstipulate leaves. It also bears a relation to *Saxifragææ*, from which it is distinguished by its stamens being hypogynous.

Its essential characters are: sepals five, persistent, equal, with an imbricated æstivation; petals five, hypogynous; stamens distinct, withering, either equal to the petals and alternate with them, or two, three, or four times as many; anthers two-celled, opening longitudinally; ovary single, sessile; styles from three to five, more or less combined; capsule one to three-celled, and with from three to five valves which bear the seeds along the middle or at their base; seeds

either naked or furnished with an arillus; embryo straight, erect, in the centre of a fleshy or cartilaginous albumen; radicle directed to the hilum.

The plants belonging to this order are delicate herbs frequently covered with glandular hairs. Their leaves are alternate, and have a circinate æstivation.

They are found in marshy and inundated places, in many parts of the world,—in Europe, East Indies, China, Cape of Good Hope, North and South America, and New Holland.

Their properties are comparatively unimportant: some of them are acrid.

The chief genera are *Drosera*, *Dionæa*, and *Drosophyllum*.

*Parnassia*, formerly included in this order, is more properly referred to *Saxifragææ*.

The genus *Drosera*, or Sundew, contains upwards of thirty species, three of which are natives of Britain. They are remarkable for their viscid glandular hairs, which detain and destroy insects. They are rather acid and slightly acrid, and are said to be poisonous to cattle. The leaves have the power of curdling milk. The name *Sundew* is derived from the circumstance of the leaves supporting small drops of a pellucid liquid like dew, even in the hottest part of the day, and in full exposure to the sun.

*Drosera rotundifolia*, *Ros solis*, or round-leaved sundew, is common in all the bogs of this country. It has a caustic juice which has been used to destroy warts or corns. *Drosera communis* of Brazil is stated to be poisonous to sheep.

A famous Italian liqueur is called *rossoli*, on account of one of the *droseras* being used in its manufacture. *Dionæa muscipula*, Venus's fly-trap, is a remarkable American plant, inhabiting the bogs of Carolina. Its leaves are all radical, and are terminated by two hemispherical lobes fringed with hairs. From the inside of each of the lobes three erect, irritable bristles proceed, which, when touched, cause the lobes to collapse suddenly like a rat-trap. By this means flies and small insects, attracted to the surface of the leaves, are frequently imprisoned and destroyed. The lobes afterwards gradually open and expand.

*Drosophyllum Lusitanicum* differs from the other *droséracææ* in growing on the barren sands of Portugal.

**DRYADEÆ** is a section of *Rosaceæ*, and will be noticed under that order.

**DRYANDRA** (R. Brown). A fine genus of greenhouse plants, natives of New Holland. Class and order *Tetrandria Monogynia*, and natural order *Proteaceæ*. Generic character: common involucrem imbricated; calyx four-cleft; stamens resting in cavities at the top of the calyx; four scales below the germen; follicular woody, and two-seeded. These plants are nearly related to the *Banksias*, and require similar treatment. Sandy loam and moor-earth suits them best. Ripened cuttings, taken off at a joint, and planted in sand on a very gentle heat, under glass, generally make roots.

**DRYPTA** (Fabricius). A genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabidæ*, and sub-family *Brachinidæ*, having the neck narrow, the head triangular, eyes prominent, the tarsi with the penultimate joint dilated, and the second joint of the antennæ long. This genus comprises but few species, one only of which, the beautiful *D. emarginata*, Fabricius, inhabits this country. It is very rare, of a rich blue colour, with the mouth, antennæ, and legs red. It is found upon the coast.

**DUCK**.—*Anas*. A genus or rather family of web-footed birds, whose habits are, generally speaking, aquatic, though some of them are more on the land, and others more exclusively on the water. For their general relations to the rest of the feathered race, we must refer the reader to the article **BIRD**, and some of the particulars of their generic character will be found in the article *ANAS*, so that all we are required to do in the present article is to notice the habits and leading characters of the more remarkable species. If we take the family of *Lamellirostral*, or flat-billed birds, in its largest extent, it includes three groups, which have all many characters in common, though they have at the same time sufficient distinctions in appearance, structure, and habit, to warrant their being classed separately; and indeed the genus or group which we are now considering admits of subdivision into sections or subgenera, and perhaps into different genera. It is not, however, our object to enter into any of the niceties of system, which are usually uninteresting and unprofitable to general readers, very nearly in proportion to the trouble which they cost those writers to whom system is of more importance than knowledge; and thus we shall notice them, as far as possible, under their common English names. The greater divisions of the flat-billed family may be said to be three—geese, swans, and ducks, the first of these we shall notice under the article *GOOSE*, and the second under the article *SWAN*, so that in the meantime we shall have to notice only the *Ducks* properly so called. We may, however, mention, as introductory to the first division which presents itself to us in the alphabetical order, that there is a regular gradation in those three branches of this extensive and important family of birds. The geese are the least aquatic of the whole; and in the finding of their food they are birds of the bank and the meadow, rather than of the stream and the lake; and though the name goose is properly applied to some of the species which are marine or inhabit the sea, yet there is no sea bird to which the term can with strict propriety be applied. The geese are the most exclusively vegetable in their feeding of the whole race, and they very rarely eat any animal substance, neither are they seed-eating birds, for their principal food is grass or the green leaves of vegetables, especially such as grow near the waters. The swans are much more aquatic in their general habits, and seldom seek their food upon the land, or extend their journeys far from the water. They are, however, birds of the fresh water only, and though they are excellent swimmers they find their food either in the floating substances which are found in rivers and ponds, or in the roots of aquatic plants. They are indeed chiefly river birds, and prefer running waters to stagnant lakes and ponds, although they can live on the latter. The natural habit of both these divisions of the family is migratory, especially in the more tropical and the more polar parts of the world. This is easily accounted for, from the simple fact of their being aquatic birds; for during the dry season the tropical waters are entirely gone, and during the winter the polar waters are sealed up by the frosts, and therefore unavailable for any kind of bird. This holds more especially with geese and swans, which are birds of the fresh or land waters, than with ducks, many of which are birds of the sea, or at least of the shores of the great collections of salt water. That this should be the case will readily appear when we consider that

the fresh waters freeze much more readily than the sea does. There are several reasons why this should be the case. In the first place the fresh waters, whether river or lake, are confined to the particular latitudes in which they are situated; and do not receive any of the influence of more tropical latitudes, except through the medium of the air and the earth. In the second place those waters are generally speaking much shallower than the sea, and therefore much more subject to seasonal changes of temperature. This circumstance is attended with very considerable effects upon the distribution of fresh water birds, and is in fact one of the most effective causes in stimulating the migration of these animals. The fresh waters are much more heated, and much more productive both of animal and of vegetable life during the summer than the waters of the sea, and on this account they attract the birds during this season; but when winter comes, the sealing up of them by the frost puts an end to the supply, and such of the birds as have not seaward habits are forced to make their retreat to warmer climates during the winter.

Ducks are much more numerous in their species and much more diversified in their characters than either of the other two divisions of the family; and taking them altogether, they are perhaps the most interesting of the whole. Upon looking back to the article *ANAS* it will be seen that ducks admit of a natural division into three groups, two of which have very distinctive characters, while the third, which is intermediate, partakes more or less of the characters of both. They are also called by different names, not only in scientific classifications, but in common language, though the general character duck, founded upon the mallard or common wild duck, may be considered as typical of the whole of them. Such as are domesticated are very interesting and very valuable birds. They are much more intelligent, and have far more expression in their appearance than any of the races of poultry; and from their habits, their food, and their manner of feeding, they are much less destructive. Naturally they are very indiscriminate in their eating, but they cannot be kept in good condition or fattened so that their food may be wholesome unless they have access to pure water. Ducks which are kept in the streets and lanes of towns, to pick up any refuse that may be there, and left to dabble in impure and stagnant waters, have never a handsome appearance, neither are they wholesome as human food, and it is worthy of remark, as showing the condition of an animal in all the stages of its being, that the eggs of those improperly treated and unwholesome ducks are as unfit for food as the birds themselves. There is another mode of keeping ducks sometimes resorted to, which renders their flesh even more rank and unwholesome than that of those which walk the streets and dabble in the kennels; and that is a practice which is but too often resorted to by those butchers which kill their own meat, of keeping ducks in the yards of their slaughter-houses, to feed upon the offal and garbage. For this purpose they have generally a small nominal pond of water in the yard, but instead of water it contains a solution of blood and all other animal impurities, in a state of putrefaction, or one approaching to it; and therefore ducks which are fattened in such places are absolutely filthy, and partake as much of the nature of poison as of that of food. While remarking on the subject, we may as well add that pigs which are as miscellaneous feeders

as ducks, and which may be said to hold pretty nearly the same rank among mammalia that ducks do among birds, are often kept in the same places, and reared in the same offensive and unwholesome way.

When ducks are kept in proper situations, have due access to water, and are fed with proper food, they are very profitable animals; and though the flavour of their flesh is peculiar, and the fat, like that of all aquatic birds, is oily and indigestible, yet they are far from being unwholesome. They are also made more healthy than poultry, and we are inclined to think that they are more prolific; so that though they are adapted only to particular situations, they are birds eminently deserving the attention of country people. If they have access to running streams, or ponds of clean water, it is always preferable; but the common horse-pond at a farm-yard answers well enough for ducks; and as the pond itself serves many useful purposes, it might not be amiss if such ponds were more numerous, not only at farm-steading, but at the cottages of labourers; as there are many little animals bred in the ponds which form wholesome and profitable food for the ducks, and at the same time cost nothing, either in expense or in trouble. Marshes and stagnant waters are objectionable in every country, because they poison the air for animal life, sour it for vegetation, and foster the growth of plants which are destructive both to the soil and to what is attempted to be grown upon it; but clear waters, on the other hand, tend equally to the healthiness and the fertility of the country.

Where there are ornamental pieces of water in pleasure grounds, ducks can always be introduced with very pleasing effect. This is the case not only with all the varieties of the common domesticated duck, but with even those species which, in their natural habits, are the most seaward, even with those which, in the wild state, are only seasonal or occasional visitants. These migratory ducks may not only be made to reside permanently on ornamental waters, but they may be tamed so as to come and be fed out of the hand, and the pochards and gannets especially, are so neat in their forms, so beautiful in their plumage, and so lively in their motions, that it is impossible not to like them. In fact, there is perhaps no race of animals which can be turned to more pleasant and more profitable account than the whole family of the ducks.

But, though the ducks are thus highly interesting in every point of view in which animals can be interesting to man, they are comparatively little known, and their history, as in the state of nature, is very obscure. It has been but too much the custom with writers on natural history that, when they have been unable to point out the proper locality of any animal at any season, they have invariably "sent it to Siberia," put it into a sort of Arctic parchment. Thus it has fared with many of the ducks; but of those which have been described as rearing their broods in the inhospitable climes of the north, there are many which have never been seen there. The habit of the whole family in the breeding season is to be retired and silent, and as all the wild ones breed in places which are not easily accessible by man, we may naturally suppose that they pass that season in places where their presence is but little suspected. The writer of this article has sometimes, when fishing on sedgy streams in the uplands, hooked a mallard instead of a trout, in situations where the voice of the wild duck

had not been heard for months; and therefore he is inclined to believe that many of those species which are described in the books as being only winter visitors are resident birds, only that they pass the summer dispersedly and in places where they have but little chance of being seen. The males are peculiarly retired and silent after the pairing time, and the female does not come abroad until she is able to launch her young ducklings upon the waters. And there is not a finer sight in the whole of living nature than this first launching of the ducklings upon that element of which they are in future to be so much the ornaments.

We shall now give a short enumeration of the leading species of these very interesting birds, beginning with those which are the most landward in their habits; and without particular attention to the three divisions which we mentioned in the article *ANAS*, however, there is so regular a gradation in the whole, that it is not very easy to say where the one begins and the other ends. There are, however, two structural divisions which are not unworthy of attention, as they form good indications of the habits of the birds. They consist of those which have the hind toe free, and those which have it webbed, and more or less connected with the inner toe in front.

The whole of the duck tribe, whether those that are more landward, or those which are more aquatic in their habits, find their food more by the sense of touch than by that of sight, and the bill is a very beautifully organised instrument. It is covered by a sentient membrane, and the edges, which come in contact, are covered with papillæ, and abundantly furnished with nerves, so that, when a duck dabbles in the water, the feeling of the bill enables it to distinguish eatable substances from the sludge and pebbles with which they are mixed, and it literally "sifts" or "pals" the matters which it catches at the bottom of the shallows.

In this character of the bill the ducks are very superior both to the geese and the swans. They are also much more compact in their plumage, and altogether better fitted for the water. They are also gayer in their colours, and in many of the species, the males especially, are very beautiful. One external character which distinguishes the greater number of the ducks from all other birds, is a spot on the secondary quills of the wings. This spot is always different in colour from the surrounding parts, and it generally is glazed with rich metallic reflections, on which account it is designated the "speculum" and the "beauty spot."

We shall now notice the leading species, beginning with those which have the hind toe plain, or without any membrane or web; these also have the legs articulated more forward, the tarsi larger and rounder, the toes shorter, and the whole foot more adapted for walking; they also have the wings larger, and, as one would say, more aerial in their structure. It does not follow from this that they are better flyers, for some of the diving ducks are very alert on the wing after they have gained their height, but the feathering of the wings in the landward ducks is much less compact than in the diving ones. The latter use the wings as a fin or paddle in making their way under water; and to adapt it for this purpose, there is a very beautiful compactness in the feathers upon both sides of the wings. The wings, and, generally speaking, the whole plumage of these birds,

is waterproof, and this quality is inherent in the feathers, of their very nature, and not produced by the application of the oil which is secreted by the gland at the rump; that the secretion of this gland is used by birds in the "preening" or trimming of those feathers, is certain; but that it is the means by which these are rendered waterproof, admits of considerable doubt; and the doubt is increased by the fact, that the feathers on the head, and those other parts which cannot be reached by the bill in preening, are just as much waterproof as those which can be so reached. It is therefore probable that the oil of the gland answers the purpose of preventing the feathers from adhering to the mandibles in the act of preening rather than that of rendering the feathers themselves waterproof afterwards. This is a subject, however, upon which information is still very much wanted, though it is one which we might suppose is very open to observation.

This arises, in a great measure, from the seasonal habits of the birds, and it is common to the whole of them. Whether they leave the country or not during the breeding time, they always disperse, and live in retirement in the fens and marshes, and, generally speaking, in situations as inaccessible as possible. Their nests are usually concealed in tall herbage, though there are instances of the same species building on trees at a considerable height above the ground. It seems, indeed, to be concealment, rather than the close vicinity of the water, which is their object at this time. In the American marshes, to which vast numbers of these birds resort when the season sets in, the nests are, we believe, chiefly upon the stumps of trees, or upon bushes, as the ground is generally flooded about the time that the nesting commences; and some specimens from that part of the world, which were at the gardens of the Zoological Society, did not make any attempt at nest-building until the keepers fell upon the contrivance of placing a stake in the pond, upon the top of which a nest was soon formed. The whole race are, indeed, exceedingly cunning birds when in a state of wild nature, although, as we have said, they are so easily tamed, and so capable of attachment.

The great length of time which the feathers of flight require before they come to maturity, is another means which prevents any of the duck tribe from being seen ranging in the summer. They are prolific birds, the eggs being from ten to eighteen. They pair in spring; the incubation lasts about thirty days, and the young break the shell in the course of May, sooner or later, according to the season and the situation; but, though the young are very active in the water, and very fond of it from their very first appearance, it is a long time before they become so completely fledged as to be able to use their wings. Before this event, the old ones have mounted, and the whole may be said to be unfit for long flight before the month of August, or even September. But the time which they spend in the fens and marshy places is that at which such places abound most in small animals, and when they are least covered with water. Thus the ducks fare plentifully; and though the growth of their very close plumage is rather a severe operation, they are said to be in better condition while moulting than many other birds are. In former times it was customary to "drive" the young ducks, and also the old ones, while moulting, by a sort of general assemblage of

the people in the fen countries; and this sport, if sport it could be called, was often so successful as that a thousand birds were taken in one day. This was most practised in Lincolnshire, and the other fen counties, and was performed with a large net; but it was considered so destructive of the breeds of the animals, that the protection of Parliament was extended to the ducks, at least for the period between the 1st of June and the 1st of October, which includes all the rearing of the young birds, and the recovery of their feathers by the old ones. The slow growth of the first feathers of the wings is a very certain means of distinguishing young birds from old ones. If, upon pulling a feather, the extremity of the pipe or barrel has blood in it, the bird is young; but if the end of the feather is dry, the bird is old, at least, it is not a year's bird, and these are always the most delicate, the rankness of flavour, and also the toughness, increasing with the age of the birds.

Ducks (we speak of them as in a state of nature only) are not game, neither are they in themselves property; and when they are in the estuaries, or otherwise on the broad waters, they are *feræ naturæ*, and may be shot, or otherwise captured, by any one who is afloat upon the water. If, however, they are on any land which is property, they belong to the proprietor while they remain there, and the taking of them in such a situation is a trespass. The places where ducks haunt, when they are in season, are not, however, the most inviting ones for genteel sportsmen, and consequently trespass is not so much attended to as in most cases.

When the ducks flock they come to the estuaries and the low flats, where a considerable extent of sludgy ground is alternately covered and left by the tide. Such places contain, during the winter months, a vast quantity of animal matter, partly that which has been washed down by the autumnal rains, which sweep a vast quantity of little animals and animal remains from the upper country, and partly also by small aquatic animals, which resort thither for the purpose of enjoying that warmer temperature which the top of the brackish water is known to possess over both the salt water of the sea and the fresh of the river. The deposits which are thus formed, and which are the grand attractions for the dabbling birds, are always great in proportion to the richness of the country, and the gentleness of the slope over which the water descends. The first of these furnishes the supply, and the second brings it down more gradually, but at the same time more copiously and completely, than if the stream ran with more violence. Rivers which flow from large lakes by short courses, and also rivers which come dashing through rocks, never form estuaries very favourable for ducks. Hence we have only to look at the map, and study the general features of a country, in order to ascertain whether its shores are or are not well adapted for the winter resort of these birds.

Now, when we look at the estuary of the Thames, and also to many parts of the south coast of England, we find that they have the duck characters in a very eminent degree. None of the rivers come from lakes; their courses are, generally speaking, on a gentle slope with out-falls or interruptions; the country through which they come is rich, and there are vast accumulations of mud. In consequence, the catching of wild ducks, in which all the species are included, though some of them are known by different names,

both popular and scientific, is carried on systematically in those places, and the quantity captured is far greater than one would suppose. There are various methods of doing this; but the chief, in point of success, is the *decoy*; and instances have been known of eight hundred pounds being cleared one year by a single decoy on the coast of Essex.

These decoys consist, in the first place, of an expanse of water, which is called the pond, and which is placed in the shelter of reeds, and, generally speaking, also of bushes. The banks of the pond are left clear for some little way, so that the birds may rest upon land, and, in short, this portion of the contrivance is made as tempting as possible, as much of the success depends upon this requisite. But, though the ducks resort to the pond in vast numbers, and pass the day in an inactive state, yet still great skill, or, at all events, practice, is required in examining the pond, because they are exceedingly watchful, take wing on the least alarm, and do not readily settle. The sense of smelling is remarkably acute in those birds, as one might naturally suppose, from the margins of their bills being so copiously supplied with nerves. In consequence of this, when it becomes necessary to approach them on the windward, it is usual to carry a little bit of burning turf, the acid smoke of which counteracts the smell of the carrier, which would be sufficient to alarm the birds, except for this precaution. The inland extremity of the pond is formed into pipes, or funnel-shaped channels, which narrow gradually, and have at the end a permanent net placed upon hoops. This net forms the trap in which the birds are taken often in vast numbers at one time. In order that the decoy may be worked in all weathers, it is necessary that there should be one to suit each of the prevailing winds. We need not farther go into the details of this mode of bird-catching. The ducks are enticed by tame ones, which are trained for the purpose; and it is from them that persons employed to entice others to their injury are called "decoy-ducks."

These birds begin to be taken in October or November, and the taking continues till the end of February, between which time and the following October operations are prohibited. Besides these decoys, there are, in the places where ducks are numerous, many of the country people who shoot them. These are called *punt-shooters*, or *punt-gunners*, in the creeks and openings of the streams in the lower part of the Thames estuary; and as they ply night and day, according as the tide answers, their labour is very severe. In the south of England it is a still more serious labour; and as the following account, drawn up by Gilpin, is very characteristic, we shall introduce it:—"The coast between Hampshire and the Isle of Wight is peculiar, consisting, at ebb-tide, of vast muddy flats, covered with green seaweed. It affords the fowler an opportunity of practising arts perhaps not elsewhere resorted to. Fowling and fishing are indeed, on this coast, commonly the employments of the same person. He who, in summer, with his line or net, plies the shores when they are overflowed by the tide, in winter, with his gun, as evening draws on, runs up in his boat among the creeks which the tide leaves in the mud-sands, and lies in patient expectation of his prey. Sea-fowl usually feed by night, when, in all their multitudes, they come down to graze on the savannahs of the shore. As the sonorous cloud advances (for their

noise in the air resembles a pack of hounds in full cry), the attentive fowler listens which way they bend their course. Perhaps he has the mortification to hear them alight at too great a distance for his gun (though of the longest barrel) to reach them, and, if he cannot edge his boat round some winding creek which is not always in his power, he despairs of success that night. Perhaps, however, he is more fortunate, and has the satisfaction to hear the airy noise approach nearer, till at length the host settles in some plain upon the edge of which his boat is moored. He now, as silently as possible, primes both his pieces anew (for he is generally double armed), and listens with all his attention. It is so dark that he can take no aim, for, if he could discern the birds, they would also see him, and, being extremely timorous, would seek some other pasture. Though they march with noise, they feed in silence; some indistinct noises, however, if the night be still, issue from so vast a concourse. He directs his piece, therefore, towards the sound, fires at a venture, and, instantly catching up his other gun, discharges it where he supposes the flock to rise on the wing. His gains for the night are now decided, and he has only to gather up his harvest. He immediately puts on his mud-pattens (flat square pieces of board, which the fowler ties to his feet, that he may not sink in the ooze), ignorant yet of his success, and goes groping about in the dark in quest of his booty, picking up sometimes many, and perhaps not one. So hardly does the poor fowler earn a few shillings, during a solitary winter night, be the weather as it comes, rain, hail, or snow, on a bleak coast, a league probably from the beach, and often liable, without great care, to be fixed in the mud, when he would become an inevitable prey to the returning tide. One of these poor fellows, I have heard say, never takes a dog with him on these expeditions, because no dog could bear the cold which he is obliged to suffer; and, after all, others frequently enjoy more from his labours than himself, for the tide often throws next day, on different parts of the shore, many of the birds which he had killed, but could not find in the night."

This hazardous occupation once led a fowler into singular distress. It happened, too, in the daytime, which shows still more forcibly the risk of such nocturnal expeditions:—"Mounted on his mud-pattens, he was traversing one of these oozy plains in search of ducks, and, being intent only on his game, suddenly found the water, which had been accelerated by some peculiar circumstance affecting the tide, had made an alarming progress around him, and he found himself completely encircled. In this desperate situation an idea struck him as the only hope of safety. He retired to that part which seemed the highest, from its being yet uncovered by water, and, striking the barrel of his long gun deep into the ooze, he resolved to hold fast by it, as well for a support as a security against the waves, and to wait the ebbing of the tide. He had reason to believe a common tide would not have flowed above his middle; but, in the midst of his reasoning on the subject, the water had now reached him. It rippled over his feet, it gained his knees, his waist, button after button was swallowed up, until at length it advanced over his shoulders. With a palpitating heart he gave himself up for lost. Still, however, he held fast by his anchor; his eye was eagerly in search of some boat which might accidentally be

passing, but none appeared. A head upon the surface of the water, and that sometimes covered by a wave, was no object to be descried from the land, at the distance of half a league; nor could he exert any sounds of distress that could be heard so far. While, as the exigence would allow, he was thus making up his mind to the terrors of certain destruction, his attention was called to a new object. He thought he saw the uppermost button of his coat begin to appear. No mariner floating on a wreck could behold approaching succour with greater transport than he felt at this transient view of the button; but the fluctuation of the water was such, and the turn of the tide so slow, that it was yet some time before he durst venture to assure himself that the button was fairly above the level of the flood. At length, a second button appearing at intervals, his sensations may rather be conceived than described, and his joy gave him spirits and resolution to support his situation four or five hours longer, until the waters had fully retired." This tale of tribulation in the flats may serve as a striking counterpart to some of those of which we read as taking place among the wild and rocky shores in regions farther to the north; and with it we shall close our general notice of this very interesting family of birds.

The species are so very numerous, and their manners are so much alike, that it will not be necessary to go into a minute description of each; but we shall notice a few in each of the two divisions. And, first,

*Ducks with the hind toe free.* The common **WILD DUCK**, or **MALLARD** (*Anas boschas*), is not perhaps the most typical duck of this division; that is to say, it is not the one which is the least aquatic in its habits, but still it is the bird from which the name is taken; and when we use the word duck, without certifying it by some epithet, it is always this one which is meant. This is also the largest in size, at least of the species which frequent this country; and though its flesh is not reckoned so great a delicacy as that of some of the smaller ducks, it is the one which appears most frequently at market. It is from the female that the general name duck is taken, while the male is the mallard, or drake.

Mallard.

The length of a full-grown mallard is about two feet, the stretch of the wings about three feet, and the weight about two pounds and a half, though there are some individuals which are heavier than this. The bill is greenish yellow, the irides hazel, and the feet

orange, with a tinge of red. The head and neck are of a dark green colour, remarkable alike for its gloss and for the fineness of the feathers. Below this there is a white collar; and the neck, breast, and shoulders, are purplish brown. The scapular feathers are a mixture of silver-white and rust colour, finely streaked with waving lines of brown. The wing-coverts are ash-coloured, with white and black on the tips, and the primary quills are dusky black. The wing-spot, or speculum, on the secondaries, is rich purple, with metallic reflections of blue and green. The lower part of the back, the rump, the tail-coverts, and the four middle tail feathers, which are curled up in the mallard, are black, with green reflections on the rump, and purple on the tail. The other feathers of the tail are dusky brown, margined with dull white. The under part, from the breast downwards, is whitish grey, with slight mottlings of brown. The duck is considerably smaller than the mallard, and wants the green and white on the head and neck. The general colour is rusty brown, lined and mottled with black, and she is without the curled feathers on the tail; but the speculum on the wing very much resembles that of the male bird.

**SHELDRAKES** (*Tadorna*). There are several varieties of these birds, the distinctions of which are tolerably well marked in a state of nature, though each variety is remarkably true to its own particular colour and marking. This is the case also with the mallard in a state of nature, though, as is more or less the case in all animals, the colours are broken down in the domesticated state. The sheldrakes have the bill much flattened toward the extremity, but the upper mandible is enlarged into a globular protuberance at the base. This character has a slight approximation to that of the goose, and there is a slight similarity in the air of the birds, though the sheldrakes are by much the more handsome birds. One character by means of which the degree of aquatic habit in different ducks may be judged of, is the particular mode in which the head is carried; for, in proportion as the ducks are in the habit of diving, they have it folded on the shoulders, and again recurved when they are in a state of repose. Their neck is an instrument to be used wholly or chiefly under the water, and thus it is held in that position in which it can most easily cleave the surface, and enable the bird to dive; whereas those species which carry the head with the neck more stiffened, use the bill more on the surface, and, generally speaking, too, they eat some portion at least of the aquatic vegetation, as well as animal matters. The sheldrake is a good confirmation of the truth of this, as it has at once most of the structure and most of the habit. There are three species of sheldrakes found in different parts of this country, and as they are less aquatic than the others, they are more resident; for it is worthy of remark, that those aquatic birds which are most seaward in their habits are also the most discursive from place to place.

The **COMMON SHELDRAKE** (*T. vulpanser*). These are handsome birds, and birds of very quiet dispositions, and not very difficult to tame in the individual, though they do not breed readily in confinement, and therefore would not be so profitable for domestic purposes as the common duck; their flesh, also, is rank in its flavour. These birds inhabit the line of the water, or near it, rather than the fens or the broad waters; they lurk in holes along the beaches,

in which the female deposits her eggs, which are from ten to fifteen, and of a white colour. The places where those nests are found bear some resemblance to the nesting-places of the eider ducks, and there is a correspondence of habit. The females of both cover their eggs with the down which they pull from their own breasts ; but, as the present species sits in less exposed situations than the eiders, a smaller quantity answers the same purpose. The male, however, takes his turn at sitting, while the female is abroad in search of her food, which is early in the morning and late in the evening, but she is never long absent from the nest. Their food appears to consist principally of insects, small crustacea, and the spawn and small fry of fishes. As they do not range any great breadth of surface in quest of food, each pair occupies some portion of the line of coast as a sort of preserve ; and as they do not flock during the great gathering of water-fowl, more than two are seldom seen together.

The lineal dimensions of the sheldrake, and also the weight, are nearly the same as those of the mallard, but the gait and markings are very different. The sheldrake has a little of the strut and swagger of the goose. The feet, and greater part of the bill, are of a reddish colour ; but the basal enlargement of the bill, the openings of the nostrils, and the nail on the tip, are black ; and we may add, that the distinctness of this nail is another approximation to the characters of the goose. The head and neck are of a beautifully rich green ; the lower part of the neck, the back, the rump, the tail-coverts, and basal part of the tail-feathers, are white. There is a band of reddish bay, which forms a collar on the lower part of the neck, and proceeds along the sides and flanks, and through this band a list of blackish brown extends to the vent. The outer half of the scapulars, and the principal quills, are black, and the secondaries glossed with a wing spot of green and purple reflections. In so far as colour is concerned, the sheldrake is one of the handsomest of our aquatic birds. The female has much more resemblance to the male than in the common wild duck, being only rather less in size, and not quite so bright in the colours.

The RUDDY SHELDRAKE (*T. rutila*). This species has the bill and the head smaller than the former, and the front and cheeks are white, extending to behind the eyes ; the remainder of the head, and upper part of the neck, rusty brown ; the body pale chestnut ; the wing-coverts white ; the primary quills, the rump, and the tail, black ; and the wing-spots green, with purple reflections. These birds are exceedingly rare in Britain, even as stragglers, for it is not the habit of the genus to straggle much ; they are, however, described as being very plentiful on the continental shores of the North Sea, and also on those of the Baltic, where the country near the coast is sandy, and the sand blown into hummocks or hillocks, or, as the French call them, *dunes*, which is very apt to be the case in such places. Among those diversified surfaces, which are generally protected, in great part, by a strong coating of bent, which gives place to more kindly herbage as the sea continues to recede, which it almost invariably does from those sandy shores. These places generally abound in rabbits and rabbit-holes, of which the sheldrakes take possession, and use them as their nesting-places ; and it is for this reason that the common sheldrake has got the name *Vulpanser*, the fox-goose.

The SHOVELLER (*Spathulea clypeata*): It is probable that there are varieties of this bird in those parts of the world which are well adapted to its habits, and at the same time far apart from each other, but only one is satisfactorily made out as an inhabitant of Europe ; and we still want a good account of the wild ducks of tropical countries, and of countries in the southern hemisphere, more especially of New Holland, which, from the quantity of rain that falls at certain seasons, and the want of any other means than evaporation to dry it up, must make that part of the world, seasonally at least, a great duck country ; and, as that is the quarter of the world in which modern discovery has found the *rara avis*, or impossible bird of the ancients, we may be prepared to meet with some novelties when the interior of that country is a little more carefully explored.

The shoveller is a very handsome bird, only its bill is disproportionately large, and very peculiar in shape. It is about three inches in length, of a black colour, widened toward the extremity ; and the fibres along the margin are so much produced, that the bill has the appearance of being surrounded all along the gape with a fringe of hairs. This form of the bill is well adapted to the habit of the animal, which is that of picking up very small animal matters in the shallows and runs of the rivers ; and as these fibrous appendages are very sensitive, they enable it to detect with great nicety all substances that are edible.

Shoveller.

The shoveller is a much more inland bird than the sheldrake, and it is also rather more discursive. It is found, we believe with very little difference of appearance, both in the eastern continent and the western ; but, so far as is known, it is a bird of the northern hemisphere, or northern migration only, and is not met with in any part of the south. There are, however, several ducks of New Holland, and some of New Zealand, which have the gape of the bill bordered with membrane, and the structure of the organ suited for nearly the same purposes as that of the shoveller ; but we are not sufficiently acquainted with the habits of those races to be able to speak with much certainty regarding them. Their bills are in general bordered with an entire membrane, or, at least, one forming a less decided fringe than that of the shoveller. On the continent of Europe it is pretty abundant, and it breeds in the marshes of the middle latitudes ; but in Britain it is not a very common bird, even in the fens. In America, it, or rather perhaps they (for there seem to be varieties in America), appear to be much more migratory than they are in the eastern

1. The first group is the

2.  $\int_{-\infty}^{\infty} f(x) \delta(x-a) dx = f(a)$

3) ... ..

$$\frac{1}{2} \left( \frac{1}{2} + \frac{1}{2} \right) = \frac{1}{2}$$

continent. This, however, does not establish any difference in the birds themselves, but may readily be accounted for in the difference of the two countries. The American summer is more dry than the European, and the American marshes, in the middle latitudes, partake of this drought, or, if they do not, they are covered with junipers and other evergreens, so that they do not answer well for the summer resort of dabbling birds. The northern latitudes of America, again, are remarkably well adapted, on account of their flatness, the abundance of water, the high temperature, and the correspondingly great production of small animals. Yet, in respect of latitude, the climates to which the shoveller moves northward, during the American summer, are not more northerly than those in which it breeds in central Europe, although, from the different character of the seasons, it ranges more in the one country than in the other. In all countries where it is known, this bird forms its nest in the tallest and thickest tufts of rushes and other aquatic herbage, and, generally, also in places which are not accessible by man, or, indeed, by any of the land mammalia. The nest is rudely formed of withered grass, collected in considerable quantity, and the female is a close sitter. The eggs are about ten or twelve in number, of a pale rust colour, and the young are led to the water by their parent as soon as they appear. At this stage they are rather uncouth, from the great development of the bill in proportion to that of the body. It is always worth while to notice the order in which the organisation of an animal is developed, or it comes to maturity, because this is one of the best guides to the habits of the animal. The young shovellers have to find their food in the water, and therefore they have the feet and the bill in a tolerably complete state when they come out of the shell, whereas the organs of flight are then in a rudimentary state; and they continue so much longer than they do in birds which are obliged to make use of the wing at an early stage of their existence. This slow production of the organs of flying, is general among birds which seek their food upon the ground, whether in the shallow waters, the marshes, the fields, or the uplands; but all of them are better provided for the use of their feet, and also of their bills, than birds of more early flight. Thus we see how well these creatures are adapted to the particular places in which they reside, and to which they are, of course, drawn by this very adaptation. The shoveller is thus described: the bill is of a brownish black colour, three inches in length, greatly widened near the extremity, closely pectinated on the sides, and furnished with a nail on the tip of each mandible; irides, bright orange; tongue large and fleshy; the inside of the upper and outside of the lower mandible are grooved so as to receive distinctly the long separated reed-like teeth; there is also a gibbosity in the two mandibles which do not meet at the sides, and this vacuity is occupied by other appendages; head and upper half of the neck, glossy, changeable green; rest of the neck and breast white passing round and nearly meeting above; whole belly dark reddish chestnut; flanks, a brownish yellow, pencilled transversely with black, between which and the vent, which is black, is a band of white; back blackish brown; exterior edges of the scapulars, white; lesser wing coverts and some of the tertials a fine light sky blue; beauty spot on the wing, a changeable resplendent bronze green, bordered above by a

band of white, and below with another of velvety black; rest of the wing, dusky, some of the tertials streaked down their middles with white; legs and feet, reddish orange. The female has the crown of the head of a dusky brown colour, and the rest of the head yellowish white, thickly spotted with dark brown, the spots on the breast being larger and crescent-shaped. The back and scapulars are dark brown with orange shafts and margins to the feathers. The under part is white with a slight reddish tinge. The wings differ little from those of the male bird, and, indeed, in all kinds of ducks, it is in the wings that the two sexes correspond the most with each other.

THE GADWALL (*Chaulioides strepera*). The gadwall is still smaller than the shoveller; like that, it is an inhabitant of marshy situations in both continents during the summer or breeding season; and it is probable that, in Europe, these birds follow the line of the central marshes rather than that of the meridian. They seldom reach the shores of Britain, and when they do it is only to the places that are most contiguous to the marshy countries on the east side of the North Sea. They are, probably, less seen in proportion to their numbers than almost any other species of duck, as their habits are very retired, and it is rarely, indeed, that they come out except during the night. In America, though the birds are not very rare, they have precisely the same habits; and as it is no easy matter to range the American marshes, the breeding places in that continent are not known. The male bird is thus described—length about nineteen inches, breadth about thirty-three, bill two inches, flat, and of a black colour; markings of the plumage exceedingly minute, giving it a sort of appearance as if it were marked with delicate stripes, and enclosed in a net-work. The ground colour of the head and neck is grey, marked with brown points; but the lower part of the neck, the back, and the breast marked with small black crescents; the scapulars and flanks pencilled with zigzag lines of black and white. Lesser coverts of the wings chestnut; greater coverts, rump, and tail coverts, black. Primary quills of the wings dusky, tail reddish, but white at the tip, which is very much pointed; under part white, and the wing-spot white, with a red margin on the one side, and a chestnut-coloured one on the other. The female differs in having the wing-covert duller, more brown on the neck and back, and wanting the crescent spots on the fore part, and the fine pencillings on the flanks and scapulars; she is also rather smaller in size than the male. The nest is always constructed in a place of great concealment, such as a thick tuft, a close bush, and sometimes the hollow of a tree; and the birds glide so softly, and at the same time so swiftly through the herbage, that they may be close at hand without the least chance of noticing them. These birds are not quite so prolific as some of the others, the eggs in a hatch being about eight or ten in number, of a greenish ash-colour. The flesh of the bird is held in much estimation. This duck, though it has not the web on the hinder toe, is a very expert diver; and for this reason it cannot be shot while swimming without the greatest difficulty; it is very watchful, and as it plunges the instant it sees the flash, it can scarcely be hit by the best directed shot.

TEAL (*Querquedula*). There are several species to which this name is applied in common, and they are remarkable for the beauty of their colours, and also for the superior flavour of their flesh; and it is probable

that some of these have been multiplied by considering difference of age and sex as difference of species.

**THE PINTAIL** (*Q. acuta*). This is a very beautiful species, both in its form and its markings,—one of the chief ornaments being the produced tail, which is of considerable length, pointed, of a black colour, glossed with rich green reflections. This very handsome species is a native both of the eastern continent and of America; and we shall not be able to give a better account of its distribution and habits in the latter continent than by the following quotation from Wilson:—"The pintail, or as it is sometimes called, the sprigtail, is a common and well-known duck in our markets, much esteemed for the excellence of its flesh, and is generally in good order. It is a shy and cautious bird, feeds in the mud flats, and shallow fresh water marshes; but rarely resides on the sea coast. It seldom dives, is very noisy, and has a kind of chattering note. When wounded, they will sometimes dive, and, coming up, conceal themselves under the bow of the boat, moving round as it moves; are vigilant in giving the alarm on the approach of the gunner, who often curses the watchfulness of the sprigtail. Some ducks, when aroused, disperse in different directions; but the sprigtails, when alarmed, cluster confusedly together as they mount, and thereby afford the sportsman a fair opportunity of raking them with advantage. They generally leave the Delaware about the middle of March on the way to their native regions, the north, where they are most numerous. On the marshy shores of some of the bays of Lake Ontario, they are often plentiful in the months of October and November. I have also met with them at Louisville, on the Ohio." In the eastern continent this bird is pretty generally distributed, though, as is the case with many of the tribe, its movements at different times of the year are not generally known. We can hardly suppose that, though it does come to the open waters in the winter season along with the rest, it retires very far to the north in the summer; because in winter it is more abundant in the south of England than in the north; while it is very rare in the south of Scotland, and hardly known in the northern parts of that country. The difference between the seasonal migration of insect-feeding birds that resort to our groves and copses, for the purpose of nidification in the summer season, and return to more southerly climates in the winter, is a subject upon which we stand in need of much additional information. We are too apt to conclude that both are subject to a similar kind produced by similar causes; and that the aquatic birds which come to us in winter, or at all events make their appearance in winter, have only a more northerly locality upon the globe than our summer migrants. The habits of the two races, their food, their time and manner of feeding, and every thing about them, are, however, so different from the others, that we can establish no well-founded analogy, or draw from the one any conclusion that will rationally apply to the other. The summer birds are, with very few exceptions, day feeders, and retire and are silent during the night; and, therefore, we can readily suppose that the longer daylight in the higher latitudes, during the summer months, must be at least one of the reasons why they resort to those latitudes. But, on the other hand, the winter birds are chiefly night feeders, or at all events feeders in the morning and evening twilights, and that they remain inactive during the day, even when they

have the severest labour to perform. It must be understood, however, that their labours in the rearing of their broods are very light compared with those of the warblers in the groves. They do not expend so much care in the forming of their nests, and at that season they have very little wing work; neither do they require to collect and carry food for their young, as is done by all birds whose habit it is to remain in the nest till their feathers of flight are nearly perfected. Thus, the rearing of a single sparrow, or swallow, perhaps, costs its parents more hard labour than the rearing of the largest brood of wild ducks. The migrations of the air birds are pretty well known; and thus it is the habits of the aquatic ones, respecting which we stand in want of most information; and when we consider that, in places suited to them, the duck family can find their food in all weathers, and bear all climates with nearly equal ease, the probability is that they will be found to breed much more indiscriminately in the humid parts of all countries, than is generally supposed.

The following is an outline of the external characters of the pintail. The bill of moderate length, black in the middle, but of a bluish colour at the sides, on which account it is called the blue-bill in some parts of America. The head is round, and the neck long and slender: the nape and hind part of the neck are dusky; and the top of the head and fore part of the neck rich dark brown; while this colour is separated from the former by a narrow white line down each side of the front. These lines are broader as they advance forward, and uniting, form a pretty large collar on the lower part of the neck, and the upper part of the breast. The remaining part of the breast, and the sides of the neck and middle of the back, are marked with fine lines of black and white; and the flanks and lower part of the back are mottled with the same colours. The scapulars are long and pointed, black in the centre, bordered with white; and the hand pendent over the bend of the closed wing. The coverts are brownish and tipped with pale orange, and the wing-spot is purple with green reflections. The quills and feathers of the tail, with the exception of the two produced and more finely-coloured ones in the middle, are dusky. The markings of this bird are altogether very beautiful; but as the form of the tail is subject to some variations in different individuals, these have been sometimes elevated into varieties without any just cause.

**COMMON TEAL** (*Q. crecca*). This is rather a small species; but its colours are very beautiful, and it is highly esteemed as food; the flesh being sometimes sold in the London market as high as five shillings a pound. The male is about fourteen inches long, twenty-three in the stretch of the wings, and about twelve ounces in weight. The female is a fourth lighter, and of a smaller size in proportion. The feet and bill are dusky; and the irides pale hazel: in the male the head and upper part of the neck bay with a broad bar of glossy variable green, bordered with a white line on the under side, extending from the bill to the hind part of the head on each side. The fore part of the neck and breast are dull white, marked with roundish black spots. The belly is white; the vent black; the coverts of the wings brown, and the quills dusky; but the outer webs of the secondaries are marked with a green spot, with a white line above and below, and a black bar over it. In the breeding season the breast of the male acquires a slight tinge of salmon-colour. The

female is all over of a brownish ash-colour, with part of the sides and the belly white, the vent also white, but with a green spot on the wing, resembling that of the male, only less bright in the colour.

The common teal spends the winter season in a state of very great concealment; so that very little is known of its breeding places. There is no doubt, however, that it breeds among the reedy pools near the margins of most of the humid districts, more especially in the richer parts of the country. Indeed, it is not uncommon in the more retired morasses in most parts of Britain, and also of the eastern part of the continent, generally, as there is nothing to give it a decided seasonal migration in latitude. It is met with as far to the north as Iceland, and as far south as between the thirtieth and fortieth parallels of latitude; and it is highly probable that its character, in every part of this wide range, is that of a resident bird. In tidal rivers the teal feed chiefly when the water is at an ebb; and are driven from their grounds as the tide rises, and as their haunts are among the tall reeds some art is required in arriving at them. The nest is carefully concealed among the herbage, and composed of a very considerable quantity of grass and stalks lined with finer ones, and sometimes with a few feathers. The eggs are numerous, being from ten to sixteen or seventeen; they are about the same size as pigeons' eggs, and of a dull yellowish colour.

**GARGANY, or SUMMER TEAL** (*Q. circia*). This species is about the same size as the common teal, which it resembles in very many of its habits, though the body is a little more elongated, and this form is generally accompanied by a more discursive habit. The leading characters of the gargany are: the bill black, the feet dusky-grey, the wing-spots greyish green, bordered with white; a white streak down the side of the neck from the eye; the back and breast purplish brown, marked with crescent-shaped dusky spots; the belly cream colour; the flanks and vent dusky, as are also the quills and tail feathers; the coverts gray with white margins; and the wing spots green, but very inconspicuous in the female, which has the upper part brown with dusky streaks. This bird is, like all the rest, chiefly seen in England during the winter only; and for this reason, though it is called "summer" teal, it is usually described as a winter visitant. In France, where it is more common than in England, it begins to build its nest in the beginning of April, whilst it begins in England a month later than this; so that there is little chance of the same individual birds, being seen in both countries; and thus it is probable that it not only breeds in some parts of the British islands, but in many of them, though no where very abundantly, and always in a very concealed and hiding manner. The pairing cry of the male bears some slight resemblance to that of the corn-crake, only it is harsher, and not nearly so loud, and it ceases before the time at which the other begins. The nest is placed on the ground among thick herbage, and the eggs, which are greenish fawn-colour, are said to be more numerous than the common teal.

**BIMACULATED TEAL** (*Q. glocians*). This species is rather larger than the common teal. Its bill is lead colour, with the margin and nail on the tip black; the feet are of a dull yellowish colour, with the webs dusky; the head, and upper part of the neck, are deep black, with rich reflections of purple and green; and on each side of the head there are two bright

spots of rust colour, one before the eye, and the other behind, and it is from these spots that it gets its common name of bimaculated, or two-spotted. The prevailing colour is ash, passing into purplish-brown, with a wing-spot of bright green, bordered with white, and divided in two by a black bar. This species is very rare indeed, even as a straggler, though it is abundant in the marshes of eastern Europe, and of western and central Asia. Its manners are therefore little known, though it is understood that both it and some other species of teal, which inhabit still further to the south-eastward in Asia, differ so little from those of the teal of western Europe, that a particular description of them is not necessary, at least for popular purposes.

**THE AMERICAN SUMMER TEAL, or SUMMER DUCK** (*Q. sponsa*). This is one of the most beautiful of the whole family of ducks, of gentle manners, and tamed without much difficulty. It inhabits the warm parts of North America, and many of the West India islands, and remains during the breeding season. Its habits differ from those of the European teal, though these probably depend more on the different nature of the two countries than of any great difference of the birds. The chief habit is, that this one builds very frequently in the hollows of old trees, in consequence of which it is called the wood-duck, while the teal of Europe builds on the ground or among the herbage. There are, however, other instances in nestling on trees in America, while the corresponding species in Europe nestle on the ground. This is a very neat and compact little species, and has been introduced into the Zoological Society's gardens by the late able and enterprising naturalist who met with so dreadful a death in the trap for wild bulls in the Sandwich Islands. These birds have bred readily in the gardens, and there is no doubt that they might be generally introduced into this country. Their chief value, however, would be as ornamental birds on the waters of pleasure-grounds, for their flesh is described as being of very inferior quality. We subjoin Wilson's description of this bird, as it is exceedingly accurate, so much so, that it does not admit of improvement. It is "nineteen inches in length, and two feet four inches in extent; bill red, margined with black; a spot of black lies between the nostrils, reaching nearly to the tip, which is also of the same colour, and furnished with a large hooked nail; irides orange red; front, crown and pendent crest, rich glossy bronze green, ending in violet, elegantly marked with a line of pure white running from the upper mandible over the eye, and with another band of white proceeding from behind the eye, both mingling their long pendent plumes with the green and violet ones, producing a rich effect; cheeks and sides of the upper neck violet; chin, throat, and collar round the neck, pure white, curving up in the form of a crescent nearly to the posterior part of the eye; the white collar is bounded below with black; breast dark violet brown, marked on the fore part with minute triangular spots of white, increasing in size until they spread into the white of the belly; each side of the breast is bounded by a large crescent of white, and that again by a broader one of deep black; sides under the wings thickly and beautifully marked with five undulating parallel lines of black on a ground of yellowish drab; the flanks are ornamented with broad alternate semi-circular bands of black and white; sides of the vent

rich light violet; tail-coverts long, of a hair-like texture at the sides, over which they descend, and of a deep black, glossed with green; back dusky bronze, reflecting green; scapulars black; tail tapering, dark glossy green above, below dusky; primaries dusky, silvery without, tipped with violet blue; secondaries greenish blue, tipped with white; wing-coverts violet blue, tipped with black; vent dusky; legs and feet yellowish red; claws strong and hooked. The female has the head slightly crested; crown dark purple; behind the eye a bar of white; chin and throat, for two inches, also white; head and neck dark drab; breast dusky brown, marked with large triangular spots of white; back dark glossy bronze brown, with some gold and greenish reflections; speculum of the wings nearly the same as in the male, but the fine pencilling of the sides, and the long hair-like tail-coverts, are wanting; the tail is also shorter.

**BLUE-WINGED AMERICAN TEAL** (*Q. discors*). This inhabits more northerly than the former species, and ranges as far to the north as the valley of the St. Lawrence, if not farther. They return early to the middle and southern states of the American union, and appear in large flocks, which squat on the mud very closely together, so that the sportsmen find them a very profitable description of game. Their flesh is also highly esteemed. They are, to a great extent, vegetable feeders, and greedily consume the seeds of Canada rice, and many other aquatic plants. They are rather small birds, measuring rather more than one foot in length, and rather less than two feet in the stretch of the wings. The front and back of the head are black; a crescent-shaped gorget of white extends from the eyes under the chin; and the rest of the head, and part of the neck, are slate-colour, with rich reflections of green and violet; the lower neck dusky, with bars of pale white; the belly brown, with dusky lines; the sides of the vent pure white, but the lower tail-coverts black; the lesser coverts clear blue, from which the common name is given; the quills dusky, the secondaries black; the wing-spot rich green; the tail pointed, and two inches longer than the closed wings. The female wants the black on the head and the rich reflections on the neck, and is rather smaller in size. These birds are exceedingly abundant in all those places which suit their habits.

The common teal also occurs in America, very little different, either in appearance or manners, from what it is in the eastern continent. It is there called the green-winged teal, to distinguish it from the others, and, as is the case in Europe, it is rarely seen during the summer months.

**WIDGEON** (*Mareca*). This bird is much larger than the teal, and its flesh also ranks higher in the estimation of epicures. The common species (*M. Penelope*) is twenty inches in length, and about twenty-three ounces in weight, or double that of the common teal. The bill is narrow, about an inch and a half long, of a bluish lead colour, but with a nail on the tip almost black; the crown of the head is cream-colour, passing nearly into white at the base of the bill; the rest of the head and the neck are light bay, the upper part and flanks marked with waving lines of black and white; the coverts of the wings brown and white; the quills dusky; the wing-spots green; the tail-feathers ash colour, except the two middle ones, which are considerably produced, pointed, and of a black colour, as are also the vent

feathers; the legs and feet are nearly the same colour as the bill. The female has the head rusty brown, mottled with black, and the back deep brown, with paler margins to the feathers.

In its general shape the widgeon more resembles the ducks, properly so called, than any of the teal; but the male is subject to considerable variations of colour, by losing his gay tints in the winter. It is understood that the nest of the widgeon, which is very little known, resembles that of the common teal; the eggs also are about the same number, and of a dull greenish grey. In England these birds are most abundant in the southern parts of the country, and they are described as advancing more toward the western shore than any others of the family which make their chief appearance in the winter season. They are very generally distributed over the continent, both in Europe and in Asia, and they range as far south as Egypt. Very little is known of their summer habits in any locality, and therefore it is not improbable that they are resident in many more places than is usually supposed.

There are several other species of fresh-water ducks, having the hind toe free, unincorporated in the membranous web of the foot, but those which we have noticed will afford to the general reader some notion of the leading characters of these birds; and, considering their numbers, and the little that is known about many of them at that season when their history is most interesting, it would neither suit the space to which we are confined, nor the purpose, of this work, to enter more at large into the details. We shall therefore proceed with a short catalogue of the leading members of the second division.

**II. WITH THE HIND TOE WEBBED.** The birds of this division carry us more to the deep waters and the sea than those of the former; and the general form of their bodies, and also the structure of their legs and wings, are all modelled to accord with this habit; the head is thicker, the bill more inclining to pointed, the neck shorter, the wings rounder and more hollow, and the whole plumage more compact, and furnished with closer down among the roots of the feathers. As they are all more of a ranging character than the land, or rather fresh-water ducks, and, generally speaking, inhabit more northerly, they are more under the influence of the seasonal action of the hemispheres, and therefore their migrations have been better observed. There are differences in their haunts when they come southward in the winter season, some proceeding more inland, and others keeping more in the sea or the estuaries; and those which have the latter habit perhaps keep more to the north, even in winter, than those which have the former. It has been thought convenient to subdivide them into several divisions, which may either be considered as genera or sub-genera.

**SCOTER** (*Oidemia*). These birds are about the size of the common mallard, but they have an enlargement more or less turgid at the base of the upper mandible. Their wings and tails are very close and stiff, and not liable to be injured when they are immersed in the water. They do not come much upon the fresh waters, but keep the shores of the sea, and find great part of their food by diving. Their breeding places are not much known, but it is supposed that they resort far to the northward in the winter. Most of them are common to the northern

shores of both continents, and found in the extreme north during the summer months. Their flesh has a rank and fishy taste, and is inferior to that of any other ducks. In former times, when the use of flesh

Scoter.

was prohibited with great strictness during lent, and in many countries still, the ecclesiastical authorities decided that scoters were a sort of fish, and so might be eaten with impunity on the meagre days and during lent.

**THE BLACK SCOTER** (*O. nigra*). The plumage of this species is entirely black, without any marking, or even any wing-spot. There is an indistinct knob at the base of the upper mandible, which, together with the streak down the middle of the mandible, is of a reddish yellow, but the rest of the bill is black, without any appearance of a nail at the tip. The orbits of the eyes are yellow, and the irides brown; the tarsi and toes of the feet are dusky, and the webs black. The female is rather less than the male, and the black has a rusty tinge. They frequent the coasts of Britain in considerable numbers during the winter season, and are understood to feed almost exclusively on shelled mollusca, for which they dive in water of considerable depth, so that they are often caught in the nets of the fishermen. Scoters come with the flood tide, and any one who has attended to the economy of nature on the shores will at once see the cause of this. When the tide ebbs, the shelled mollusca shut themselves up, or, where they have that habit, plunge down into the sand or mud; but when the tide returns, they come up and open their shells, and thus they are readily captured by the scoters, which are found numerous and active in proportion as their peculiar food is abundant. This species is found equally in all places of the North Seas.

**THE VELVET SCOTER** (*O. fusca*) is perhaps not quite so abundant as the black scoter, and the one

Velvet Scoter.

has often been confounded with the other, as they are about the same size, and differ little in their habits. They may, however, be distinguished from each other

without any difficulty. The plumage of the male is velvet black, without any gloss, and there is a crescent-shaped spot of white under each eye, and wing-spots of the same colour. The irides, the tarsi, and the toes, are also reddish; the bill dusky at the base and the margins, but dull yellow in the greater part. The black on the female is not so intense, and the under part of that sex has a whitish tinge. They are also a little larger in size than the black scoter. Their flesh, like that of the former, is rather rank in the flavour, but still it is readily eaten by those northern people who depend chiefly upon the sea for subsistence.

**THE SOLE SCOTER** (*O. perspicilla*). This species is in a great measure confined to the American shores, but is found equally on both sides of the continent, and thus it may be expected in the adjacent part of the north-east of Asia. It migrates with the seasons, and does not appear to differ much in its habits from the other two species, but it is readily distinguished by its markings. Its general colour is black, and there is no spot on the wing, but the nape of the neck, and a band across the eyes, are white; the tarsi and toes are blood-red, and the bill is yellowish-red, with a grey tip, and darker margins, which are more pectinated than in the other scoters. This species may be said to be unknown on the more southerly coasts of Britain, and it is very rare even on the most northerly isles, being seldom seen as any other than a merely straggling specimen, in all probability helped on its way by the north-west gales. It is necessary, however, to speak with caution of what may or may not be present on those rocky and formidable shores, when the north sea is up, and lashing them with all the violence of a wintry tempest, because these are not times at which observations can be made, and therefore there may be many birds which visit those places quite unknown to naturalists.

**POCHARD** (*Fuligula*). The birds of this sub-genus are much more interesting to those who are fond of water-fowl than the scoters. They are short and dumpy in their forms, but exceedingly well made both for swimming and for diving. When they visit Britain in the winter, they are much more inland or fresh-water ducks than the scoters; and therefore, though their breeding places are not much known, the probability is, that they are the fresh-water marshes and lakes of the polar countries rather than the shores of the sea. There are a good many species that come regularly to the fresh waters of Britain, and also to those places of the estuaries to which we have so often referred as the chief haunts of water-fowls. They are also pretty generally distributed over both continents, though it has not been ascertained that any of them pass the summer far to the south in either continent. They are understood, however, to be much more easily kept in a state of domestication than those diving ducks which are more partial to the sea; and as they are very handsome and lively upon the water, as well as very excellent eating, they are worthy of more attention than they have hitherto received.

**THE RED-HEADED POCHARD** (*F. ferina*). This duck is common to the two continents; and used in England, where it comes in the winter, to be called the red-headed wigeon. It is, also, from some of its colours, called the "dun bird," by the fowlers and dealers. The weight of this duck is about a pound and three-quarters: its length nineteen inches, and

the extent of its wings about thirty. Its bill is rather broader than that of the wigeon, of a deep lead colour, and with the tip black; the tarsi are also of a red colour, and the irides orange. The head and neck are deep chestnut, the feathers on the top of the head being considerably produced. The lower part of the neck, the breast, and the upper part of the back, are dusky black; the scapulars and coverts next the body greyish white, pencilled with delicate lines of black; the exterior coverts and quills are dusky brown; the belly ash-coloured and brown; and the tail, which is short, and consists of twelve feathers, is of a deep grey, inclining to black. The female has the upper part of the head dusky brown; the remainder of the head and part of the neck pale blackish brown; the breast brownish ash, closely margined with whitish; and the back dark ash with little or no appearance of pencilling. The bill, wings, and feet, are nearly the same as in the male.

This species comes very plentifully to the oozy runs and partially concealed waters of those districts where ducks are caught in so great numbers; and therefore it is plentiful in the London markets, especially in Leadenhall, which is the grand mart for all this race of birds. They are taken in decoys, but not in the same kind of decoys or in the same manner as the mallards, which are the game principally alluded to, in noticing the structure of decoys in a former part of this article. A pond is prepared for the pochards, as well as for the others, and a situation is chosen which shall possess in the most eminent degree the three attractions of quietness, cover, and proximity to the feeding grounds; but this pond does not terminate in pipes with tunnel nets permanently stretched over them. It is technically called a flight pond, because the birds are captured when they are first on the wing; and the nets, by which this is effected, are so placed as that they may act to windward of the birds, as ducks always fly to windward when they take the wing. The net is kept ready extended on the top of the reeds or other cover, upon poles, which by means of a counterpoise at the bottom, can be instantly erected, upon withdrawing the pins, by which they are held down; when this is done, the poles rise and elevate the net to the height of about thirty feet; and this takes place just as the birds are alarmed, and made to take the wing. They strike against the net, are thrown off their balance, and are thrown on the ground, which, all under the net, is formed into little pens or traps, into which the birds fall, and are unable again to take the wing. The numbers caught in this way, at one skilful application of the net, are often perfectly astonishing; and they tumble into the pens one over the other, till the lower ones are killed, and sometimes pressed nearly flat with the burden of their companions. It is mentioned that, on some parts of the Essex coast, a wagon load of pochards have been taken at one drop of the net. This species is common to the two continents, appearing in the temperate climates only during the winter; and resorting to the more northerly ones in the breeding season. It is, properly speaking, a fresh water duck; but it never, in its winter haunts at least, ranges to any great distance from the sea. This, however, is no proof, that it does not breed far inland in the marshes; because food is most abundant in those marshes in the summer; while the portions of the rivers next the sea, in the rich flat countries, abound most in food during the winter, even in countries

where the inland and upland pools and marshes are not frozen at that season.

CANVASS-BACK POCHARD (*F. valisineria*). This is an American species, very abundant in the States during the season of ducks; by far the most celebrated in that country; and, indeed, according to Wilson's account, which is very minute and circumstantial, it is the most celebrated as an article of food, of all the web-footed birds. It is entirely unknown in the British islands, and also, so far as we are aware, in the whole of the eastern continent. It is thus described by Wilson: "the canvass-back is two feet long, and three feet in extent, and, when in good order, weighs three pounds; the bill is large, rising high in the head, three inches in length, and one inch and three-eighths thick at the base, of a glossy black; eye very small; irides dark red; cheeks and fore part of the head and greater part of the neck, bright glossy reddish chestnut, ending in a broad space of black that covers the upper part of the breast, and spreads round to the back; both scapulars and tertials white, faintly marked with an infinite number of transverse waving lines, or points, as if done with a pencil; whole lower parts of the breast, also the belly white, slightly pencilled in the same manner, scarcely perceptible on the breast, pretty thick towards the vent; wing coverts, grey, with numerous specks, blackish; primaries and secondaries, pale slate, two or three of the latter of which, nearest the body, are finely edged with deep velvety black; the former dusky at the tips; tail very short, pointed, consisting of fourteen feathers of a hoary brown; vent and tail-coverts, black; lining of the wing, white; legs and feet, very pale ash; the latter three inches in width, a circumstance which partly accounts for its great powers of swimming. The female is somewhat less than the male, and weighs three pounds and three-quarters; the crown is blackish brown; breast, as far as the black extends on the male, dull brown, skirted in places with pale drab; back dusky white, crossed with fine waving lines; belly of the same dull white, pencilled like the back; wings, feet, and bill, as in the male; tail-coverts, dusky; vent, white, waved with brown. When they are on the shores in the eastern states of America, these birds feed principally upon a succulent, aquatic plant, which abounds very much in many parts of the waters there. They arrive in a very lean condition in October; but as they resort only to those places in which their favourite food is abundant, they soon get very fat. Wilson says—"They are excellent divers, and swim with great speed and agility. They sometimes assemble in such multitudes as to cover several acres of the river, and when they rise suddenly, produce a noise resembling thunder. They float about these shoals, diving and tearing up the grass by the roots, which is the only part they eat. They are extremely shy, and can rarely be approached, unless by stratagem. When wounded in the wing, they dive to such prodigious distances, and with such rapidity, continuing it so perseveringly, and with such cunning and active vigour, as almost always to render the pursuit hopeless. From the great demand for these ducks, and the high price they uniformly bring in market, various modes are practised to get within gun-shot of them. The most successful way is said to be decoying them to the shore by means of a dog, while the gunner lies closely concealed in a proper situation. The dog, if properly trained, plays backwards and forwards along the margin of the water,

and the ducks, observing his manœuvres, enticed perhaps by curiosity, gradually approach the shore, until they are sometimes within twenty or thirty yards of the spot where the gunner lies concealed, and from which he rakes them first on the water, and then as they rise. This method is called *tolling them in*. If the ducks seem difficult to decoy, any glaring object, such as a red handkerchief, is fixed round the dog's middle or to his tail; and this rarely fails to attract them. Sometimes, by moonlight, the sportsman directs his skiff towards a flock whose position he had previously ascertained, keeping within the projecting shadow of some wood, bank, or headland, and paddles along so silently, and imperceptibly, as often to approach within fifteen or twenty yards of a flock of many thousands, among whom he generally makes great slaughter. So much are those birds esteemed, that every stratagem which the fowler can invent is had recourse to for the capture of them; and they are so numerous that those employed in this way are generally very successful.

THE SCAUP POCHARD (*F. marila*). This species is also a native of both continents, having nearly the same habits as the others, breeding in the northern marshes, and migrating southward in the winter. It is smaller than the last mentioned, or than the red-headed pochard, being about eighteen inches long and twenty-nine in the stretch of the wings, and weighing rather more than a pound and a half. The colours, both of the naked parts and of the plumage are subject to variations at different ages, and also in different individuals. In general the bill is bluish, the feet lead colour, the irides golden yellow, and the wing-spots white. The head, which is tumid, is glossy green half way down the nape, the neck, breast, and lower part of the hind neck black; the back and scapulars white, with waving lines of black; primary quills brownish black; secondaries white with black tips; belly white, marked with black near the vent; vent feathers, rump, and tail coverts black, and tail feathers dusky brown. The female has the front and sides of the head white, the rest of the head brownish, and the general colour inclining more to brown in the male bird. In consequence of this colour of the female, the species is sometimes called the white-faced duck. Their principal food is understood to be small shelled mollusca and aquatic worms; in search of which they range the flat banks in the bays and estuaries; but they are indiscriminate in their feeding, and very easily tamed.

WHITE-EYED POCHARD (*F. nyroca*). This species gets its name from the whiteness of the irides, which give it a peculiar expression. It is about seventeen inches in length, and two pounds weight. Head and all the fore part rust colour, with a collar of darker, and a white spot on the chin. Back and wings black, glossed with purple, and marked with small red spots. Primary quills dusky; secondaries with white bases, and black tips, forming a white and black wing-spot. Tail dusky brown. The female has the head brown, and the back dusky, and without the reflections. This species has the same habits as the other pochards; and, like them, it resorts to the "ducking grounds" during the winter; but it appears to come to England from an eastern migration, and is exceedingly, if not altogether, unknown in Scotland.

TUFTED POCHARD (*F. cristata*). This species gets its name from a crest of about two inches in length, which is pendent from the hind part of the head. It is a

migrant bird like the others, though, probably, it does not range so far; because though not so common in this country as several of the others, it continues longer, chiefly on the fresh waters, and more inland than the other pochards. It is about a foot and a half long, and weighs twenty-six ounces. Bill and legs black; the former broadened toward the tip, and with a black nail; irides dull, yet low; the head, neck, and crest black; but with rich reflections of green and purple. The middle of the back and the breast black, without any reflection; the scapulars and sides mottled black and grey; lower breast and belly pure white; flanks and vent feathers black; tail feathers dusky, wings black, but having a white spot on the secondaries. The female and the young are dusky brown on those places which answer to the white in the male, and they are without any crest.

RED-CRESTED POCHARD (*F. rufina*). This species belongs chiefly or exclusively to the eastern hemisphere, ranging as far as the mountains of central Asia. It is much less known in western Europe; and its appearance in Britain is very rare, and always in the south-east, where a small flock may be seen at long intervals. From what is known of its habits, it appears to be less a sea bird than any other of the pochards. The male is a particularly handsome bird. The bill is red with a white nail, and the feet red with black webs. The nail of the bill is much produced and pointed, and extended over the lower mandible, like a hook. The head and crest, the latter composed of long silky feathers and very handsome, are rich reddish chestnut with purple reflections. The hind part of the head, breast, and middle of the belly, are brown, and the vent feathers black; the back is brownish ash, with two crescent spots of white on the scapulars, which nearly meet. The sides are white, mottled with brown at the margins; the wing spot is also white, and the rump and upper coverts of the tail green with purple reflections. The female has no crest, and the head and upper part are more inclining to brown than in the male.

There are several other varieties of pochards, or, at least, of diving ducks, analogous to them, especially on the northern shores of America, and in some of the Antarctic countries; but too little is known respecting them for their being admitted into a merely popular list.

LONG-TAILED HARELD (*Harelda glacialis*). This species is in many respects analogous to the pochards; it is a diving duck, and makes its appearance at the same season, and it is like them, common to the colder regions of the whole northern hemisphere. It has sometimes been confounded with the pintail, principally, we believe, because both agree in having their tails longer than any other ducks; but still they are different in their habits, and belong to separate divisions. This species has the bill very short, and black, with a transverse red stripe; a large patch of chestnut brown on the sides of the neck. Length from twenty to twenty-one inches, owing to the elongation of the middle tail feathers; but the bird is only about the size of a pigeon. This bird inhabits Europe, Asia, and America; frequenting both the interior lakes and the sea shores of those quarters of the world. The birds of this species do not, like many other of the tribes, entirely quit their northern haunts in winter, but considerable numbers reside permanently in the polar regions. Numerous flocks, however, spread themselves southward in the winter from Greenland

and Hudson's Bay, as far as New York, in America; and from Iceland and Spitzbergen, over Lapland, the Russian dominions, Sweden, Norway, and the northern parts of the British Isles, in Europe. The bands which visit the Orkneys, appear in October, and continue there till April. About sunset they are seen in large companies, going to and returning from the bays, in which they frequently pass the night, making a noise, which, in frosty weather, may be heard at the distance of some miles. They are rather scarce in England, to which they resort only in very hard winters, and even then in small straggling parties. They fly swiftly, but seldom to a great distance, making a loud and singular cry. They are expert divers, and supposed to live chiefly on shell-fish. The female places her nest among the grass, near the water, and like the eider duck, lines it with the fine down of her own body. In the northern parts of the American continent, these ducks are found in vast numbers during the summer; but as they are more marine in their habits than most of the species, they do not move farther to the south in winter, at least in their more numerous masses, than they are compelled to by the freezing up of the shoals and shallows, where they seek their food. Their nests are described as being hid in the grass or other coarse herbage; but never at any very great distance from the sea. On their southward migrations, they seldom resort to the inland marshes, but take short flights from channel to channel in the broken parts of the shores. Their style of flight is rapid, and they utter a singular, and when in numbers, a very loud cry while on the wing. Their flesh is rank in flavour, and little esteemed; and thus they are apt to take their flights and carry on their fishing without being much disturbed.

**GARROTS** (*Clangula*). These are northern species, found, we believe, most abundantly in the northern parts of the Atlantic, and therefore more plentiful on the shores of America than on those of Europe, even in the winter months, when they quit their polar habitations, or rather are driven from them by the ice. The position of the Scandinavian mountains forms a sort of barrier, excluding the polar birds of the Atlantic from the north of continental Europe; and besides, the waters of the Baltic do not partake of any of the advantages of the Gulf Stream, and the fertility which it brings; and this farther arrests the progress of those birds, which otherwise might be much more abundant in the marshy districts of central Europe during the winter. The general characters of the garrots are: the bill short and narrow; the feathers on the scapulars produced, pointed, and apart from each other; the third quills passing over the primaries in the closed wing, but not being loose and pendent as they are in some birds. They are rather small in size, but very active.

**THE GOLDEN EYE, or COMMON GARROT** (*C. vulgaris*). This species is named from the colour of the iris of the eye, which is very brilliant, of a bright yellow colour, and shines like a little spot of gold upon the side of the head. They swim swiftly and beautifully, dive with great expertness, and live upon aquatic animals, including reptiles, and even water mice. On the wing their motion is very swift, but their flight is usually low, and accompanied by a peculiar whistling or clangulous noise. Their breeding places in the eastern continent are little known; but in America they are said to build on the stumps and in the hollows of old trees. The golden eye is about eighteen inches

long, and thirty in the stretch of the wings, and weighs about a pound and three quarters. The bill is of a bluish colour. The upper part of the neck, and the head, the feathers on the top of which are very thick and much produced, forming a sort of crest, but not a pendent one, are of a rich glossy green, with the exception of a white spot just behind the gape. Below the green there is a collar of deep velvet black, below which the whole under part is pure white, with the exception of a few black feathers on the flanks and thighs. The middle of the back and the rump black, and the tail brownish; some of the scapular feathers produced and of a white colour, the rest are black, as are also the tertiary quills, which cross over the primaries. General colour of the wings brownish black, with the coverts and secondaries white crossed on the middle by a black bar. The female is brown on the head and dusky on the back, with paler margins to the feathers. The males do not attain the full colours of their mature plumage until the second year.

**HARLEQUIN GARROT** (*C. histrionica*). This species is named from the similarly contrasted colours of its coat. The harlequin inhabits the same parts of the world as its congener, the golden eye, but it inhabits more northerly, and does not appear in the low latitudes of either continent in even the severest winters. This does not arise from its being a scarce bird in the high latitudes, but from its polar habits. It is abundant on the shores of the arctic ocean both in America and in Siberia, and also in the islands to the south of Behring's Strait. Indeed, excepting as an occasional straggler, it appears to keep, at all seasons, as near to the polar ice as the water is open. In Britain we believe it has never once appeared in the south, or even on the main land of Scotland, though it may at some times be driven upon those inhospitable shores near Cape Rath, which are not very accessible to observation during the winter storms. It is sometimes seen in the more remote isles of the north, though only a straggler. On the coast of America it is a little more common, because that coast lies nearer to the Arctic countries in which it breeds; but even there it is very rare on the shores of the midland states, and quite unknown on those of the southern.

It is smaller than the golden eye, and much more peculiar in its markings, though that also is a gaily coloured bird. Its length is about seventeen inches, the stretch of its wings about twenty-six, and its weight, a pound, or perhaps a little more. The general colour of the upper part of the body is a deep glossy green, which in some lights appears almost black, but in others it throws out brilliant reflections of lighter green and of purple. This green is marked with lines of white and black, very conspicuous and well defined; and placed differently from similar markings on any other birds. On each side of the head there is a curved white line, beginning near the nape, passing over the eye to the gape, and returning on the cheek, where it has a reddish tinge. This white curve is margined on its under side by a very narrow line of intense velvet black, without any reflections, which contrasts strongly with the ground-colour of the head, notwithstanding the deep tint of the green on that. A circular spot of white is placed immediately behind the eye; and from a little behind that, a white line passes from the head down the side of the neck, and another narrow line of white,

Alpine Mastiff

margined by black, almost surrounds the lower neck as a sort of collar. These distinct arches of white, with the convex sides upward, reach from the shoulder to the breast, the one next the shoulder having a black margin on the under side, and the remaining two a similar margin on the upper. These arches form nearly a continuous band, and the portion of the breast which they enclose is of a bluish ash colour, relieved by lighter margins to the feathers. The remainder of the under part is brown, with a tinge of red toward the flanks. The scapular feathers are pretty long, pointed, distinctly separated from each other, of a white colour in the middle, but with black margins. The wings and tail are dusky black, and the wing-spot blue, with purple reflections. The bill is dusky, the feet are bluish, and the irides brown. The female has a rusty tinge on the head and neck, the upper part brownish, and the under part dull white. The nesting-places are said to be in the herbage on the marshy places of the Arctic shores, and also near the pools of fresh water in the same region, but never at any great distance from the sea. If we take the whole race of ducks, in the order of their latitudes from the equator to the pole, the harlequin may be considered as the last, and it certainly is one of the most beautiful. Its flesh is also described as being excellent.

**EIDERS** (*Somateria*). On a strictly systematic arrangement of the duck family, it is not very easy to determine with perfect satisfaction what should be the place of this highly interesting genus. They are much larger birds than any of the other ducks, being as weighty as the average of the geese. They have also some peculiarities in their structure, and more perhaps in their manners. All the species, for we are acquainted with at least three of them, are remarkable for the immense coating of down by means of which they are protected from the cold; and thus, though they are gentle creatures, and to appearance delicate, they are perhaps more proof against the severity of the northern winter than most of the family. In the southern parts of England they are unknown, but there a few which inhabit the Fern islands on the coast of Northumberland; and there are some also on a few of the small islets in the Firth of Forth. From there, northward, they are not met with, because the shores are not suited to their habits; but in the Orkneys, the Shetland Isles, and some of the more remote places of the Hebrides, they are found in greater numbers. Wherever they are met with, they may be considered as resident birds rather than as wanderers; for, though they take long flights when out of the breeding season, they are understood to return to the same haunts.

It is in the more dreary and inhospitable parts of the north that those birds are found in the greatest numbers, and where they may be said to be quite at home. In Iceland, in the Fern islands, and in other northerly places, they serve many important purposes, and the inhabitants would find their comfort much diminished if they were deprived of the eiders. Their eggs and their flesh serve for food; their skins form under clothing, which is proof against very severe cold; and, without very serious injury to the birds, a vast quantity of the finest down is procured from them every year. So firm and elastic is this down, that the same quantity which can be compressed and concealed between the two hands will serve to stuff a quilt or coverlet, which, while it has hardly the

weight of a feather, has more warmth than the finest blanket. We must, however, shortly notice the species.

**COMMON EIDER** (*S. mollissima*). This is the best known species; it is the one of which a few specimens are found on the British shores, and also the one which may be said to be domesticated by the northern people, though its domestication costs them no expense, as the birds feed entirely on sea-weed, and other products of that element.

Eider Duck.

The common eider has been known from very remote antiquity, and its manners have been well described by almost all who have written on the natural history of the north. During the summer months they are very abundant on all the isles in the Greenland seas; and they are also met with floating in pairs or solitary at great distances from the land, but in these cases they are usually near the ice. In spring they swim in flocks, and in fine weather one of those flocks is a very beautiful sight. They ride high in the water, their attitudes are elegant, and their motion, though swift, is smooth and gliding, and apparently performed with great ease. They can also make excursions on the wing; and, though they are heavy birds, it has been estimated that they can move along, when they are on their high flight, at the rate of ninety miles an hour, without apparent effort or fatigue.

But it is perhaps when they are on their breeding grounds that their manners are most interesting. The nest is made on the ground, composed of marine plants, and lined with down of exquisite fineness, which the female plucks from her own body. The eggs are usually four, of a pale olive green, and rather longer than those of a common duck. About Iceland the eider duck generally build their nests on small islands not far from the shore, and sometimes even near the dwellings of the natives, who treat them with so much attention and kindness as to render them nearly tame. Two females will sometimes lay their eggs in the same nest, in which case they always agree remarkably well. As long as the female is sitting, the male continues on the water near the shore, but as soon as the young are hatched he leaves them. The mother, however, remains with them a considerable time longer; and it is curious to observe her attention in leading them out of the nest almost as soon as they creep from the eggs. Having conducted them to the water's edge, she takes them

on her back; and swims a few yards with them, when she dives, and leaves them on the surface to take care of themselves; and they are seldom afterwards seen on land. When the natives come to the nest, they carefully remove the female, and take away the superfluous down and eggs. They then replace the mother, and she begins to lay afresh, covering the eggs with new down; and when she can afford no more, the male comes to her assistance, and covers the eggs with his own down, which is white. When the young ones leave the nest, it is once more plundered. The best down and most eggs are got during the first three weeks of their laying; and it has been generally observed that they lay the greatest number of eggs in rainy weather. One female, during the time of laying, usually yields half a pound of down, which, however, is reduced one half after it is cleaned. It is probable that the eiders, at least in very many of their localities, depend upon the current of the Atlantic for their food, and also for the materials for the nests; and that, while this circulating of the ocean waters brings the sports or germs of the sea-weed, and also the small animals which are buried in these annually renewed deposits, the drift-grass brought by the same current serves the birds for the materials of their nests, just as the drift-wood serves the people for their domestic purposes. This wood furnishes an abundant supply in places where not a tree grows; and the drift-grass, in like manner, brings a store for the birds to those dreary rocks upon which there is not a particle of land vegetation.

The length of the male eider is about two feet three, and the stretch of the wings about three feet; the head is large, and the bill very peculiar; it is three inches long, and two plates from the side of it extend up the forehead, with feathers between them; the colour of this bill is dull yellow; the top of the head is velvet black, divided posteriorly by a white line on each side; a portion of the side of the head is pea-green, divided by a white patch; the plumage from this part to the throat is very thick, and the feathers appear as if the ends were cut off; the upper part of the neck, back, scapulars, wing-coverts, and sides of the rump, are pure white, the under part black; the tail, and the primary and secondary quills, dusky black; the tertiaries yellowish white, and curving down over the closed wing; the tarsi are short, and of a yellow colour, as are also the toes, but the webs are black. The female is considerably different; it is smaller; the bill does not rise so high on the forehead, and the general colour is dark reddish drab, with lighter blotches, and spots of black, and the under part dusky, mottled with black.

**THE KING EIDER** (*S. spectabilis*). This species does not come so far southward as the common eider, and therefore its history is less known, though it is probable that some individuals breed in the more remote British islands. It may readily be distinguished both by the bill and the plumage, and is somewhat less than the other. The lateral prolongations of the bill on the forehead are arched, ridged, and furrowed; the colour of the bill and feet is a bright reddish orange, but the terminal parts of the plates toward the forehead are black; the feathers over the eye, at the base of the bill, and partly down the sides of the neck, are bright green, meeting in front, and gradually passing into whitish on the chin, which is marked with an angular bar of black; the top of the head and back of the neck are ash-coloured;

the middle of the back black; the coverts dusky, with a patch of white in the centre; the quills black, and the tertiaries curled over them; the tail, which is short and wedge-shaped, black, as are also the belly and vent, but the lower neck and breast are whitish. The female is smaller, of a brown and dusky colour, has the plates of the bill less conspicuous, and the tertiaries not curled over the wing.

**WESTERN EIDER** (*S. dispar*). This is an inhabitant of the North Pacific, though it sometimes finds its way to the Atlantic, and, in a solitary instance, has been found in Britain. Bill black, hooked at the tip; ground-colour of the head and neck white, with a green band on the forehead, and another on the nape, and a black collar, and the chin black; upper part black, pied with white, with the tertiaries much produced, and curving gracefully over the wings; under part white forwards, and brown to the rear; feet lead-coloured, large and strong; the whole body elongated, and the head slender.

Such is an outline of the interesting family of the ducks; but it would take much space, and more labour and research, to fill up that outline with the requisite minuteness of detail.

**DUCKWEED** is the *Lemma* of Linnæus, and that well-known floating plant which forms "the green mantle of the standing pool." It belongs to *Monoclea Diandria*, and to the natural order *Fluviales*. There are four species, all indigenous to Britain.

**DULCAMARA** is the *Solanum dulcamara* of Linnæus, a common British hedge plant, otherwise called bitter-sweet.

**DUMB-CANE** is the *Caladium sequinum* of Ventenat, so called from its reputed property of taking away the power of speech, if eaten.

**DURANTA** (Linnæus). Tropical evergreen shrubs, belonging to *Didynanea Angiospermia*, and to the natural order *Verbenaceæ*. Generic character: calyx tubular; rather truncated, five-cleft; corolla funnel-shaped, tube curved, limb five-lobed, lobes nearly equal, spreading; stamens within the tube; anthers roundish; style filiform; stigma thickened; drupe united to the calyx. This is a pretty genus, and thrives under the ordinary management, flowering freely, and is raised from cuttings.

**DUVALIA** (Haworth). A genus of succulent plants, natives of the Cape of Good Hope. Linnæan class and order, *Pentandria Digynia*, and natural order, *Asclepiadeæ*. These plants require to be potted in dry sandy soil, mixed with lime rubbish. Very little water is necessary, for if it becomes stagnant about the roots, the plant is apt to rot. They are propagated by cuttings, which should be dried in the sun till the wound is healed, and then placed in dry soil to make roots.

**DYNASTES** (MacLeay; SCARABÆUS, Linnæus, and of the modern French authors). A genus of coleopterous insects, belonging to the section *Pentamera*, sub-section *Lamellicornes*, and family *Dynastidae* of MacLeay, in which the body is very large and thick, the outer edge of the jaws sinuated or toothed, and the lower jaws corneous and toothed. This genus comprises the largest and most robust of the insect tribes, and many of the species are armed with remarkable spines upon the head or thorax, which gives them a very formidable appearance. They are, nevertheless, quite harmless in their habits, residing in their early stages on the decaying bark of trees, their larvæ resembling those of the cock-chaffer and

rose-chaffer. See CETONIIDÆ. Other gigantic insects are inhabitants of tropical regions, to whose entomological fauna they impart a very decided appearance. None are found in this country, and only one in France. The larger kinds are found in Guiana, India, &c.; those, however, found in more moderate climates, as in China, in the neighbourhood of Buenos Ayres, &c., are generally of smaller size.

According to M. Lacordaire, whose researches in entomology in South America have been very extensive, the habits of the various species are nearly alike. During the day they conceal themselves in holes in the ground, or on the decaying trunks of trees; or they may occasionally be seen creeping about the footpaths in forests. At the approach of night they quit their retreats, and fly about the trees in the same manner as our *Melolontha vulgaris* and *solstitialis*. M. Lacordaire supposes that it is then that they take their food; but analogy would induce us to suppose that, like the *Melolonthæ*, it is during the day that they feed, and that their nocturnal flights are for the purpose of seeking their mates. They produce a shrill noise by rubbing an elytra against the abdomen. The females are generally more common than the males, and are for the most part destitute of those remarkable horns which the males exhibit, and which, so far as we yet know, seem to be of no use to the insect as means of defence. One of the species, *Dynastes tityus*, is recorded by Say, the American entomologist, to have occurred on one occasion in such numbers as to have caused no little surprise in the neighbourhood of Philadelphia, where they were discovered, although during eighteen years an industrious collector had only previously met with two individuals. They were found in the cavity of an old cherry tree, which was blown down by the wind.

Of the larger and more remarkable species, the Hercules and Elephant beetles may especially be noticed. The former is black and polished, with greyish elytra. In the males the thorax is protruded into a thick and curved horn bent downwards at the tip, and woolly beneath, being as long as the whole body. The head is also armed with a similar but shorter horn, bent upwards at the tip, so as to come in contact with the former; the entire length of this curious beetle is nearly six inches:

*Dynastes Hercules.*

The fine species figured for the first time in our plate of "Beetles," from the collection of the Rev. F. W. Hope, F.R.S., is named by that gentleman *Dynastes Hardwickei*, in honour of general Hardwicke, the celebrated Indian naturalist, by whom it was brought from Nepal. It is thus described by Mr. Hope, in his Synopsis of Nepalese Coleoptera, "*Niger, scutellatus, thorace quadricorn, cornu capitis erecto, recurvo, elytris castaneis, pedibusque nigris.*" Black, with a scutellum, the thorax with four rather short horns, the head with an erect horn bent backwards

at the tip, the elytra chestnut coloured, and the legs black. It is rather more than two inches long, and one inch wide.

**DYSCHIRIUS** (Panzer). A genus, or rather sub-genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabidæ*, and subfamily *Scaritidæ*. The species are of small size, and closely allied to *Clivina*, from which they differ in having the thorax globose, and the anterior tibiae not, or but rarely, palmated at the tip. They are of small size, and are found in damp situations, on the sea coast, and under stones, &c.; the species, of which there are nearly a dozen British species, require a more minute investigation than has hitherto been bestowed upon them.

**DYSDERA** (Latreille). A genus of spiders, belonging to the quadripulmonariæ of Latreille, having six eyes placed in a curve resembling a horse-shoe, open in front, the mouth-claws very large, and produced in front; the maxillæ straight, and dilated at the place of insertion of the palpi. The type is the *Dysdera erythrina* of Latreille, a species not uncommonly met with in England under stones.

**DYTICIDÆ**. A family of coleopterous insects, belonging to the section *Pentamera*, sub-section *Adephaga*, and comprising the aquatic species of voracious beetles, which formed in the Linnean system the genus *Dyticus* (or as it is occasionally, but improperly spelt, *Dytiscus*). These insects are distinguished by their oval and depressed form, the moderate length and slenderness of the antennæ, the structure of the legs, formed for swimming, &c. An examination of the external structure of the body of these animals discovers a solidity of organisation of the various parts, from which great strength is necessarily imparted to the insects. A sternum (or breast bone, external), of very large size, of which the parts are so constructed as to form a perfect piece of armour; a pair of flattened coxæ, dilated and produced into a point behind (generally mistaken for the extremities of the sternum itself); posterior legs thick and compressed, and a strong fringe of hairs to all the legs, are the organs which chiefly tend to enable these insects to make their way through an element in which they are the scourge of a mass of animals more weak than themselves. They are, in fact, the aquatic representatives of the equally voracious land *Carabidæ*—all kinds of food seems good to them. They swim with great agility, and often make their way out of the water, not only towards the night, but in the hot sunshine. De Geer kept some a long time in glass vases filled with water, feeding them upon flies and spiders. One day one of them attacked and devoured a large leach, but this food disagreed with it, as the following day large morsels of the animal were discharged from the mouth, and the *Dyticus* soon afterwards paid for its gluttony with its life. Esper kept one of the *Dyticus marginalis* in the same manner, feeding it once a week, or sometimes oftener, with a piece of raw beef the size of a nut, from which it completely sucked the juices. It would sometimes fast for several weeks together. It killed an individual of *Hydrous piceus*, a water beetle larger than itself, piercing it between its head and thorax, the only part of the body not protected by the horny covering of the animal.

This family comprises a great number of species, of which the majority are of small or minute size.—These, of course, have not attracted so much of the attention of observers as the large species, whose

habits and transformations have been recorded. The eggs of the *D. marginalis*, according to Roesel, are hatched ten or twelve days after they are deposited. In four or five days, the larva is nearly half an inch long, when it sheds its skin for the first time. A second moult takes place in about the same time, when the insect has attained twice its former size: when full-grown it is about two inches long. In summer fifteen days is sufficient for it to attain this size, and to pass into the pupa state, and in fifteen or twenty more days the perfect insect is produced. These larvæ are found in all waters, and when the period of their transformation to the pupa state is arrived, they bury themselves in the earth at the margin of the water in which they are produced, and form an oval cell, in which they are transformed to inactive pupæ.

The mouth of the voracious larvæ is not constructed in the same manner as that of the larvæ of most coleopterous insects; instead of the mandibles being short and fixed near together, they are placed at the sides of the front of the head, being very long, slender, curved, and acute at the tips, having a channel along its surface with a terminal orifice, these hooks are struck into the body of the prey of the larva, and by their assistance it is enabled to suck those fluids for its own support. The respiration of these larvæ is effected by an apparatus placed at the extremity of the body, so that in general it is to be perceived suspended at the surface of the water by means of two hirsute filaments at the tail, between which the two breathing spiracles are to be seen; hence, when the larva rises to the surface of the water, these spiracles are immediately brought into contact with the air, and the ciliæ of these appendages quickly drying, serve as a buoy to retain the larva in this situation, which, however, it is enabled instantly to quit by giving to its body a vermicular motion, and beating the water with its posterior part, the fringe of which serves as an oar. When the larva is full grown, it creeps out of the water, and Lyonnet at this period observed that it possessed the ordinary number of spiracles along the sides of the body, which, of course could not have been previously employed (the animal breathing by its tail as before stated), but which are given to the animal to be employed when it has quitted the water to become a pupa. Lyonnet satisfactorily demonstrated that this was the fact by again placing in the water one of those larvæ, when bubbles of air escaped from each of the breathing pores, a circumstance which had not previously taken place.

A, the larva. B, the perfect *Dytiscus marginalis*.

The period of coupling of these insects is during the winter and spring months, after which the female, according to Lyonnet, deposits eggs more than once, each laying consisting of from forty to fifty eggs;

they are deposited without any care in the water singly, the period of oviposition lasting several days. An idea of the form of the larvæ and perfect insect will be more readily obtained from the figures which we here give of them than from a detailed description.

The similarity of circumstances in which these insects are placed renders it necessary that they should exhibit but little variation in structure. The number of species is but small, but they are dispersed over a wide extent of country. For instance, a large species of *Cybister* (of which genus, with one exception, the species are extra-European) is found from Senegal to New Holland, being observed at Guinea, the Cape of Good Hope, Madagascar, Mauritius, and the Indian Archipelago. The species of the genus *Dytiscus* seem exclusively to inhabit Europe and the north of America, of which latter country the productions in many respects closely approximate those of Europe.

The sexes of these insects exhibit various peculiarities. The elytra of the males are smooth and finely punctured; whereas those of the females, in many of the larger species, have several deep furrows, which are covered with a coating of hairs. The males in some of the latter species have the three basal joints of the tarsi of the fore legs very broad, dilated, convex above, and furnished below with fine hairs. By means of this instrument the male retains its situation during coupling. In the perfect insect the respiratory apparatus does not differ from that of other beetles; but, in order to bring the spiracles into contact with the air, the beetle is obliged from time to time to ascend to the surface of the water, which is easily effected by discontinuing the motions of the feet, when the body, which is lighter than the water, immediately ascends to the surface. In this situation, with the head downwards, and the legs stretched out at right angles, the extremity of the body is pushed above the surface of the water, the elytra are slightly raised at the tips from the upper surface of the abdomen, and a sufficient supply of air is introduced beneath the elytra, which are then closed. If the insects wish to remain beneath the surface of the water with their legs unemployed, they are compelled to lay hold of aquatic plants with their tarsi.

Since the time of Linnæus, numerous generic divisions have been separated from the Linnæan genus; that of *Haliphys*, distinguished by several remarkable peculiarities, having been first established by Latreille, Clairville, Leach, and other entomologists, have added to their number. The genera of which the family is at present composed are, *Haliphys*, *Cnemidotus*, *Pelobius*, *Anisomera*, *Hyphydrus*, *Hygrotus*, *Hydroporus*, *Noterus*, *Hydrocanthus*, *Coplotomus*, *Laccophilus*, *Agabus*, *Colymbetes* (with numerous subgenera), *Cybister*, *Acilius*, *Hydaticus*, *Dytiscus*, *Leionotus*, and *Eunectes*; the majority of which comprise species inhabitants of this country.

The typical genus, *Dytiscus*, as now restricted, comprises the largest species in the family, the anterior tarsi of which are dilated in the males, the elytra of the females furrowed; the posterior tibiae are of moderate size, and the claws didactyle. There are eight or nine British species, of which the most abundant is the *Dytiscus marginalis* of Linnæus, of an olive-black colour; the margins of the thorax and elytra ochreous, with an obscure lunula of yellow near the extremity of the latter. It varies from one to seventeen inches in length.

**EAGLE** (*Aquila*). A genus of accipitres or rapacious birds, belonging to the division of diurnal preys, and included in the great genus *Falco* of the older naturalists. But their characters are not only sufficient for ranking them as a separate genus, but might in strict system warrant the separation of them into two or more genera or subgenera, at least if the classification were to be made very minutely characteristic of their habits. This part of the subject is, however, foreign to our plan; and as their relation to the rest of the rapacious birds, and some of their structural peculiarities have been noticed in the articles ACCIPITRES, AQUILA, and BIRD, we may restrict this article to the peculiarities of the leading species, of which we shall endeavour to give a popular account, as brief, but at the same time as comprehensive as our limits will admit.

The eagle among birds, like the lion among beasts, has long got credit for qualities which it does not possess, and which it could not possess without a direct violation of the system and purpose of nature. As the lion was named and described as the king of beasts, the monarch of the forest and the wild, so the eagle was elevated to the government of the sky, and made the queen, or rather (for they gave to the male that superiority which really belongs to the female) the king of the feathered race. Not only this, but as the eagle is capable of soaring aloft, it was made the companion of the Gods, the constant associate of Jupiter himself, and in some sort the emblem of his power; and now that Jupiter has gone the way of all idols, and the eagle still remains in localities which generally have a great deal of wild grandeur and rude sublimity about them, the eagle has become the monument of her fabled master, and is still "the bird of Jove."

In so far as natural history is concerned, those fables are as absurd as they are difficult to be got rid of by those who are fond of romancing; but they have their use in throwing light upon the feelings of men in the more rude and early stages of human society. The eagle, like the lion, was gratuitously endowed with a great many virtues, being set down as the most courageous, the most noble-minded, and the most generous of birds,—as one in short who could do nothing at all calculated to lessen the majesty of a monarch. Whereas, in fact, unless in so far as that instinct which has been given them in order that they might answer those appointed purposes in wild nature, prompts them to kill and eat, eagles are not only indolent, but they are, in reality, cowardly birds; that is, when their purpose is accomplished, they seek retirement, and relapse into a state of perfect inaction. That they must have done so in the early stages of their history, the same as at the present time, does not admit of any doubt; for how much soever the dispositions and opinions of men may improve, or fall off in the course of those fluctuations, with the accounts of which the annals of the race are chequered, the other animals have no opinions, and partake not either of the improvement or of the falling off, in consequence of any direct influence of the human race, in one way or another. It is no doubt true, that when society improves, and extends its arts and its cultivation, so as to require protection to cultivated vegetables from those animals upon which the predatory tribes feed, and protection to those domesticated animals on which the others would feed, the predatory races fall off in numbers,

and ultimately become extinct, before the progress of human art.

This fact, and any one who attends to the evidence, will be able to discover that it really belongs to the system of nature, and is not brought about by human exertions in exterminating the animals, though this may in many cases assist, is sufficient to convince any one that there is really an opposition between those destroying animals and man, viewing him even simply in the light of a consumer of the fruits of the earth,—that, when man is not there, and nature is yet bountiful in consequence of the elements of fertility abounding in any place, those powerful animals, whether they prey upon the earth, in the air, or in the waters, are an essential part of the exuberance of wild nature, and have important functions to perform in its economy. If we may so express it, when the locality is of that generous and bountiful character, in which it would best reward the labours of the cultivators, but is yet without the cultivator to earn and to enjoy the reward, the lion, the eagle, the wolf, or whatever may be the predatory animal whose structure and habits are best adapted to the place, is really in the character of *locum tenens* for man; and in this respect it may be considered as the keeper of wild nature for man, until he shall have arrived at the majority of knowledge and of art, and shall be able to take the government on his own shoulders, and prevent the bounty of nature from being lost, at the same time that he makes his own advances in intelligence and enjoyment.

Such being the case, all attributing to animals of any disposition in any way analogous either to any virtue or to any vice of man, and all attributing to them of any plan or purpose, or any combining together, for the weal or the woe of each other, according to any forethought plan, is an error in principle, tending to jumble together the conduct of irrational and irresponsible creatures, and the conduct of rational and responsible man: and thus, not only destroying the philosophy of both in a natural history point of view, but laying a sure foundation for scepticism and doubt, by shaking man's belief in the existence of his immortal spirit and thereby laying the axe to the root of all sound morality, all conduct upon principle, and all hope that the mental acquirements, which man obtains in this life shall not be lost, and buried with him in the grave for ever.

The extent of mischief which has been done by publishing those groundless analogies between the irrational animals and the human race, is incalculable; and, unfortunately, this mischief is not confined to those who, in the waywardness of a wandering philosophy, or in the dread of future punishment, which they seem conscious that they deserve, attack the hopes of immortality avowedly, or with the purpose proclaimed in the preceding view, how much soever the parties may strive to hide it. Were it confined to these, its pernicious effects would be within a compass comparatively narrow; and the avowment or even the implication of such a purpose, would destroy the bad effect; because the world would see that such arguers had motives and grounds which they concealed, and did not fully and fairly examine the whole state of things, and draw their conclusions, and form their judgments from this examination. When, however, the general tone, and even the avowed purpose is to maintain the doctrines upon which these false analogies are calculated to cast doubt, the doubt so

produced is of a much more inveterate and dangerous character. This is, in fact, exactly a parallel to a case which breaks down in the hands of an advocate who is at once able and willing; and the public, who are the jury in this case, are sure to come to the same decisions on its merits, as the empaneled jury do on those of the other,—that the case has no foundation.

This is not only incidental to the natural history of any one species, genus, or class of animals; but it is of so much more importance to the real happiness of men than any thing connected with the details of natural history, that we should not feel our duty discharged, if we did not allude to it upon those occasions where the imputation of modes and motives of action similar to those of man, have been most frequently and generally imputed to the other animals. The kingship which has been given to eagles, or rather the supposed noble and honourable qualities which they have been said to possess, in consequence of this imaginary kingship, are of some use in throwing light upon the progressive natural history of man himself. The only attributes which could be observed in these animals, are great strength or power, when the necessities of the individual animal render it necessary. Other than this, there could be nothing actually observed, for other than this there is nothing to observe; and the additional and nobler qualities gratuitously given must have been given in consequence of a disposition in men in a rude state to attribute every virtue to those who were powerful enough to destroy even though the power was used for working destruction in the most cruel and atrocious manner. Therefore, those royal animals throw some light upon the characters of the kings of early history, from their resemblance to whom they got their titles to royalty; and as we have the animals still unchanged, we can, perhaps, better arrive at the general characters of those early rulers by this means than by any other.

In this, we must admit, there is at least some advantage to be derived, from the fact of human qualities and dispositions having been attributed to animals; for those qualities and dispositions could have been attributed only from the circumstance of a felt analogy between the simple action of the parties compared, at a time when the difference between acting by reason and purpose, and acting by instinct, was but imperfectly understood. Such being the case, whenever we are put in possession of the disposition and character which were imputed to the animal, and then find by observation what the real character of the animal in a state of nature is; we can take the latter as a constant quantity, as the same in the same race, at all stages of the world's history; and from this invariable standard, we can discover what must have been the sentiments of the people who imputed this qualities, in regard to the moral nature of human actions; and in this way, the study of animals, compared with the ancient opinions of them would tell us far more of the characters of the nations of antiquity than are handed down to us even by the most correct and philosophical historians of the human race. This is an use to which the study of animated nature has not hitherto been applied, although it is a very valuable one. At the same time, however, it is one which cannot be prosecuted with accuracy and success, unless we abandon as entirely fabulous or imaginary all analogy of kind between man and the animals. There is no doubt, however, that this study would repay with information, equally correct and curious, and at the

same time highly valuable as an auxiliary in the study of the human race, the labour of any one who would enter upon it with the requisite degree of knowledge, and work it out with due patience and impartiality.

As it is now, we shall just mention two instances, which may be taken as counterparts, of the noble qualities which were so long ascribed by every body to the lion and the eagle, and which are still in common circulation, and no doubt extensively credited by those whose knowledge of natural history extends no further than having read some of the books of mere description. The ass and the goose are, by universal consent, made the very emblems of stupidity and folly; so much so, that their very names have become so closely linked with these unhappy conditions that to apply any of them to a man would be considered a violation of the rules of ordinary politeness, even in society of not the most scrupulous description. But the ass, so far from being a stupid animal, is a wonderfully sagacious one; and though in this country, where it is abandoned to the least reputable part of society, and badly fed, and worse treated, it is a comparatively slow and sometimes a sullen animal, yet there is not perhaps one of the domesticated mammalia which is so totally free from vice. It is the most enduring, the most patient, the most hard-working, the most temperate, and the most inoffensive of all animals; and as these qualities have not been destroyed, even by cruel neglect and even by more cruel treatment, we must conclude that they are natural to the animal, that they form its disposition as a race, and that they were its observed qualities at the time when its name became a synonyme for stupidity. Now, if any one will consider this list of qualities, and reflect what the moral condition of mankind must have been when these were held as being expressive of stupidity, which all mankind dislike in the application to themselves, a conclusion will be arrived at not very favourable to society, because the opposite qualities, turbulence, wrangling, and all the worst passions and their worst effects, must at that time have been accounted the signs of wisdom. The case of the goose is nearly similar. The goose is a vegetable feeder, and attacks no animal, however weak, though it defends its young with some resolution; and the goose, so far from being a stupid animal, is perhaps the most intelligent and the most susceptible of sensation in the whole poultry yard. This is not the place for entering upon details; but there are many instances recorded of more attachment on the part of this bird than of almost any other of the feathered race. The sum of its character may be said to be mildness; and when, in consequence of this character, its name became a synonyme for folly, it requires no argument or investigation to discover what qualities and what conduct must have been held in the highest estimation among the human race.

We have deemed it necessary to premise these few observations in order that, by detaching them from all fancied analogy to man, we might be enabled to view the eagles in their own natural character, and as a most interesting and in some respects a most wonderful branch of animated nature. When we view them in this respect, they become as instructive as they are delusive while mixed up with man; and thus, by freeing ourselves from absurdity and error, we clear the ground for an instructive perusal of one of the most striking pages in nature's volume, and we may add that there are many bright pages in that

volume which we close to our own view by absurdities of the same class with those of which we have been endeavouring to point out the impropriety and mischievous effects.

The great distinction between the eagles and all other birds of prey, overlooking the differences in particular parts of their structure, is the possession of superior strength, together with superior power of endurance. Some of the vultures are probably birds of larger dimensions than the most formidable of the eagles; and no eagle can be compared with the superior falcons, either in elegance of form or in power of wing; but there is a degree of strength for short efforts, about the eagles, which places them in nearly the same relation to the falcons as the lion and the tiger stand in to those predatory mammalia which run down their game by swiftness of foot. There is nothing in the action of an eagle at all comparable to the beautiful gliding of the kite, the rapid forward flight of the peregrine, or the lightning rush of the jer-falcon. But still the eagle in the air is a splendid bird, and one knows hardly whether most to admire, the terrible stoop of those species which descend from the top of the sky in the open wastes, to strike their prey upon the ground, or of those which descend upon the surface of the waters for the capture of fish. In all the species, the rush of the eagle is of comparatively short duration, for though some of them are described as giving chase on the wing, and striking their prey in the air, yet these are habits of falcons and hawks rather than of eagles. Eagles are, however, found in so many and such different localities in wild nature, that there are great differences of habit in those which are found in different places. The mountaineer, which inhabits the pinnacles of the rocks, nestles on the most inaccessible ledges, beats the upper valleys and moors for prey, preys only or chiefly on living animals, and strikes them on the ground, aided by an impetus obtained by a rush of many fathoms through the sky, in which the specific gravity of the bird aids the descent of the wing, ought perhaps to be considered as the typical eagle. There are, however, some of the most powerful ones which inhabit the forests of the warmer regions, or rather perhaps the margins of those forests; and they unite in so far the habits both of the vulture and the hawk with those of the species which we are disposed to regard as the typical eagle. It is probable, also, that when the hawking action of giving chase on the wing, and the vulture propensity of eating carrion, are joined with the more single predatory habit of the typical species, there is also joined less or more of the disposition to feed upon fish. It is probable, also, that the typical eagle depends more upon the eye in finding her prey than is the case with any of those of mixed habit; and it is worthy of remark that this most typical of the race is confined to the wildest and the barest pastures, the more lofty mountains in Scotland, perhaps some spots in Ireland, the rocky elevations which mark the forests of Scandinavia, and the elevated wild and bleak districts of the Alps and the Pyrenees. On the other hand, those species which are found on the margins of the tropical forests, however powerful they may be, and however active in the finding of their prey, have an apparent softness about them, even when in a state of the most powerful excitement, which this eagle of the mountain rocks never displays, even though in a state of repose. Nor is there any doubt

that though some of these are of greater size and armed with larger beaks and talons, there is no eagle of the mixed character which would be able to contend in single contact with the golden eagle of the wild mountains of Europe. It is not in the size of the animal, or the form of the instrument, that the superior power resides, it is in the spirit and the muscular energy; and when these are great, they tell in the whole character and expression, and in the case of birds, even in the very plumage. Any one who has an opportunity, and this opportunity may be had in the gardens of the London Zoological Society, of comparing together, the harpy eagle of central America and the golden eagle of Europe, will have no difficulty in perceiving that, though the former is the larger bird, and also has the beak and the claws most formidable, yet that there is a fire in the eye, and a firmness in the whole structure and air of the latter, which leaves not the smallest doubt as to which would be the victor, in the event of each bringing the whole of its strength against the other upon equal terms. Nor is it difficult, from the different modes in which the two must find their food, to see that this is a wise adaptation in nature. The mountain eagle has to contend with all the violence of the mountain storm, while she sits upon the pinnacle of the rock, beaten by the wind and pelted by the snow. Her common flight in ranging for her prey is not rapid or performed with effort; and from the loftiness of her flight, the keenness of her eye, and the few objects which there are to intercept her vision, her floating is neither long nor laborious. When her effort comes, however, it is an extreme one; and, therefore, whether she has to maintain her position against the violence of the elements, or descend upon her victim with that rapidity which makes the viewless air appear to shiver for fathoms in the rear of her, her muscular exertions must be greater than even that which is required for the spring of the lion or the tiger. The other eagle, from the more rich and more sheltered pasture, from having to beat about where trees break her horizon, to catch the larger birds on the wing, and to seize monkeys and other tree animals while they are on the branches, requires a frame, not so knit and wound up for the single effort, but one which is more flexible, and can more readily accommodate itself to the varied circumstances of a chequered scene.

The characters of the eagle are:—The bill very strong, straight in the basal part, and curved only toward the point; the feet very strong, supplied with powerful muscles, and in the mountain eagles always feathered on the tarsi. The toes very stout; and the claws powerful and very much arched. The particular form of the foot and toe varies a good deal with the habits of the birds. If the habit is to kill the prey only or chiefly on the ground, the outer toe is not reversible; though, even in them, it turns outwards until it is at right angles to the axis of the body. In these the under sides of the claws are grooved, so as to form two trenchant or cutting edges upon each claw, which tear or lacerate while the strong muscles are drawing the toes together with great force. When the foot is of this structure, it is the sole instrument employed in killing the prey; and the beak is reserved for rending it after it has been killed. If, on the other hand, the habit is chiefly or exclusively a fishing one, the outer toe is reversible, and the claws want the groove, and are rounded on the under sides. If, again, some of the disposition of the hawk is mingled, the

claws are sharper at their points, and the bill is more arched at the base. In fact, there is a great deal of nicety in the adaptation of the weapons of these birds to the nature of their prey, and the mode of their catching and killing it; but all the varieties of this adaptation would require a very intimate knowledge of the habits of the birds—more, indeed, than it is possible to obtain, from the wild nature of the general haunts of these birds, and the short time that any one of them can be seen in a state of nature.—The wings of eagles are, generally speaking, very long, though less so in proportion to the weight of the birds than in some others of the order. They are remarkably broad and firm. The fourth and fifth quills are the longest; and the third, second, and first get gradually shorter, which gives roundness, but at the same time firmness to the extremity of the wing. The shafts and tubes of the quills, and even the webs are much firmer than in any other birds, and this firmness extends in a great measure to the whole of the plumage, so that no force of the wind, or even any ordinary contact with sprays and twigs, or even conflict on the ground with the more powerful prey, can very much ruffle the plumage of an eagle. In the species which fish, and which have to plunge into the water in the seizing of their prey, and sometimes when that prey is heavy, to struggle with it on the surface, the plumage on the under part of the body, and the under sides of the wings, is very close and compact, bearing no inconsiderable resemblance to that of water birds.

The power of enduring hunger is as remarkable in the eagles as any of their other powers, notwithstanding the boldness with which they prey, and the rapacity with which they feed. The one habit is as necessary to them as the other; for, with the exception of those which depend on the sea, which knows no scarcity except when it is sealed up by the frost, there are seasons at which all of them find but little food on their pastures. Upon the mountain tops there are few animals during the depth of the snowy season, and of the few that are there, hardly any come abroad. It is probable that, at those times, the eagles doze in their eyries without any action, and consequently with very little waste of the system; for it does not appear that mountain eagles come far down from their airy heights even at these times of the year; at the same time, the bones of a perished eagle are rarely found when the season turns, and the snow clears off. They appear, indeed, to be but little migratory at any season. They choose their ground, and, having once chosen it, they keep it; nor does it appear that they are much in the habit of invading the territories of each other.

They all live in pairs, which are never at any great distance from each other, though it is said that, when one of the pair meets with any casualty, the other one wanders off, never to return to the same locality, though a second pair may take possession of the deserted eyerie. The pairs inhabit more or less wide of each other, according to the nature of the pasture, but they are never very near neighbours; nor does it appear that they have any social instinct save that which keeps the pair together, and it is merely the instinct of continuing the race, and nothing more. The attachment to the young, the industry of the old birds in feeding them, and the determination with which both defend them, are all very great; but their apparent paternal attachments and labours are

nothing but results of the same lasting instinct, only as long as the young are helpless, and not only ceasing, but turning to the opposite propensities as soon as the young have acquired sufficient wing and strength for finding their own food. There is a moral, or, at all events, a physiological lesson, that may be drawn from this. The *storge* in the human race is an animal principle as well as it is in eagles; and hence we find it very strong in parents, who are, at the same time, not only neglecting to take those steps which would ensure the mental and moral worth, and consequently future respectability of their children, but following habitually those courses which tend, of necessity, to the very opposite results. This is most conspicuous on the part of ill-educated mothers, who may be often seen pawing and fondling their children, as a tigress paws and fondles her cubs, while she is not only neglecting their minds, but thwarting the father in all his efforts to provide for them. We mention the mother, because there is little or none of this merely animal *storge* in the other sex, as is proved by the total neglect of young children by the males among savages. The moral of the whole is, that the principle, or the instinct, does not carry the human female to perfection, while it invariably does the female eagle. She never slackens her attention till her offspring are fit for the world, while, notwithstanding the strength of the animal impulse, the woman who acts upon impulse alone unfits her offspring for the world by the whole tenor of her conduct. The reader will see that out of this arises a very powerful argument for the existence of mind, and one equally powerful for the necessity of moral as well as technical education. Such is one of the lessons we may learn at the eyrie of the eagle.

When the young eagles are driven off from the parental eyrie, it is not known whether they are yet in possession of the pairing instinct, or at what age they pair. That most of them do pair before they undergo their last change of plumage is highly probable, and this is one of the reasons why one species of eagle has in so many instances been multiplied into two. Even now, it is by no means made out how many of these differently coloured eagles, which are met with in the same locality, are of different species, and how many are exactly the same; and very few years have elapsed since the daughter of the golden eagle of our own country was invariably set down in the books as a different species from the mother.

The systematic natural history of eagles is thus a matter of great difficulty and much uncertainty; and when we attempt to get at their manners, so as to classify them according to these, we are not in a much more hopeful predicament. Every body knows the name, and there are many who have opportunities of seeing the birds, not only stuffed in glass cases but alive in cages; but these convey very little information on that part respecting which information is the most desirable—the manners of eagles in free nature; and he who could procure materials for one year's history of a wild eagle would merit the thanks of every lover of birds.

It is generally understood that eagles live to a very great age, Klein says to not less than four hundred years, though, of course, nobody ever kept a journal of the transactions of an eagle for anything like that period. Instances are quoted, however, of eagles having lived for long periods in a state of con-

Golden Eagle

finement; and there is a spot on one of the southern slopes of the Grampians, in Scotland, where the population, that is, the race of people, has not been changed for many centuries, and there a pair of eagles continue to build in a lofty and inaccessible crag, which, according to the concurrent testimony of the people, the same pair have inhabited beyond the period of human tradition, which, in reference to that very crag, is as old as the days of Sir William Wallace, which may be estimated at about the year 1300, or 535 years ago. Whether the eagles were there in the days of Sir William, it is not easy to say; but if they were, it is probable that the patriotic knight might have caused them some temporary alarm; for the tradition, universally believed in the district, states, that he descended the face of the crag, nearly perpendicular, and at least a thousand feet high, alighted safely at the bottom, stormed, single-handed, a neighbouring fortalice, then held by the invading English, put the whole garrison to the sword, rallied the country people, led them down Glen Esk, whetted his sword anew upon a great stone by the road-side, met the English army some ten miles down, and totally defeated it, all within the compass of the same four-and-twenty hours. A hint was indeed thrown out, in supplement, by the narrator of this adventure, with whom the writer of the present article went to visit this same pair of eagles as nearly as possible, that the royal birds came there along with Sir William, having scented, by anticipation, the feast of the slain that was to ensue, and that they have remained there in honour of the feast, and in gratitude to the illustrious cause; but the reciter had the candour to add, that he knew few who believed this part of the narration, and could not really find in his heart to believe it himself. Be that as it may, it is certain that this pair of eagles have been there for a very long period, for the people are both observant and intelligent. Their little glen is quite secluded, and depends on its own productions and occurrences for topics of conversation, and every thing that has happened for a century or two is borne in perfect memory. There is another circumstance. Those ancient eagles of Wallace's Crag were much paler in the colour than most of those which I (that pronoun may be used once) have seen in the same mountains; and, while it is the habit of the species to lose some white in its progress to maturity, it is also understood to become hoary, through old age, before it ceases to spread its broad wings in the upper air, and to shoot down in its stoop, like a frost-rent fragment from the beetling summit of the crag.

The four distinctive kinds of eagles into which the whole race might be arranged, if we had sufficient data for the determining of all their characters, which, unfortunately for this very interesting branch of ornithology, we have not, would be *Eagles*, *par excellence*, meaning thereby the golden eagle, and the rest of the more powerful mountaineers which agree most closely with it in habit; *Vulture Eagles*, or those which are more in the vicinity of the woods, and which, though large in size, are not so compactly built, or proportionately so strong; *Fishing Eagles*, or those which chiefly or partially levy their contributions upon the waters; and *Hawk Eagles*, or those of smaller size, and comparatively feeblér powers. We shall not, however, attempt to make any systematic arrangement of the eagles into these groups, because the characters of many, indeed the greater

number of them, are too imperfectly known for enabling us to make such an arrangement anything like perfect; and so we must content ourselves with notices of the leading species in an order which is of necessity somewhat miscellaneous.

**GOLDEN EAGLE** (*A. chrysaëta*). Some notion may be formed of the appearance and expression of this magnificent bird by examining the figure in the plate, "BIRDS OF PREY." That figure represents the eagle in the act of clutching, with the gripe of death, the prey upon which she has just alighted in her terrible stoop from the top of the sky. The aim which she takes on these occasions is so unerring, her descent so rapid, and her stroke so powerful, that if the prey is not a very large animal, the death-wound is given by the shock. It seldom happens, however, that the life of the prey becomes extinct in the instant; and as the bird never touches the prey with her beak, or even deigns to look at it after the stroke, until all motion of life in it has ceased to the feeling which she has of it with her feet, that where she can be seen in the act of preying, which is not often, even in those countries where eagles are most numerous, she is found to remain for some time in the attitude represented by the artist. During the whole of this time all her weight is borne upon the feet, and all her energy concentrated in the clutch of the talons. The head is elevated and drawn backward in what one would be disposed to call an attitude of disdain, though in reality it is nothing more than the bearing of that part, so as that the whole weight may tell upon the foot or feet engaged in completing the work of death. The wings are held half expanded and shivering, and the tail is spread to the full width of its fan-like expansion. When all motion in the prey has ceased, preparation is made for the feast, unless the prey is to be borne off to the eyrie, which is generally the case when there are eaglets there; if not, and if the bird is not disturbed, it is done on the spot, and the process is gone about in a very systematic manner. If one of those mammalia on which eagles feed, as a lamb or a mountain hare—but it is rarely the former, as eagles do not hover much over places where there are shepherds and flocks—one foot is planted on the throat, and the other on the lower part of the pelvis, and a stroke of the bill serves to divide the skin along the whole of the under part. The skin is then dexterously turned back on both sides, and the chest and abdomen are opened, the blood and vital parts being the first that are devoured. Then follow the rest; and if the eagle is hungry, which is generally the case, as nothing but the craving of appetite, or the instinct of feeding the young, can overcome the native indolence of these birds, the whole of the flesh, usually bones and all, is devoured upon the spot. How the golden eagle may deal with feathered prey, the writer of this article is unable to say, never having seen her at such a meal in a state of wild nature; but, as she goes so well to work in skinning mammalia, there is little doubt that she is equally dexterous in the depulmation of birds.

Here it may not be amiss to mention an error with regard to both birds and beasts of prey, which is so very prevalent as to have become an idiomatic part of almost every language, to the users of which such animals are known, and who have advanced so far in the use of thought and of speech, as to have figurative as well as literal meanings to their words. Those more powerful of the carnivorous races, whether of

mammalia or birds, are represented as though they were constantly engaged in the work of death and destruction; that the lion in the desert is for ever roaring and rending; and that the mountain air can never rest for the wing of the eagle; that her shadow is a constant ensign of dread, and her cry a never-ceasing sound of fear. This is the general notion, but nothing can be wider of the fact, and nothing would be more in opposition to the whole tenor of nature's economy. It is the small powers and the feeble exertions in nature that are never at rest. Those creeping currents of the air which we can hardly call breezes, and which tell only upon the leaves of the aspen, are never at rest; but storms are not frequent, and a hurricane, even in what may be called the hurricane countries, is an event of comparatively rare occurrence. Just so among birds. The sparrow is necessarily catching caterpillars, and picking up those crumbs and that refuse and waste which would become offensive if allowed to accumulate, while, on the average of the year, the golden eagle does not feed once a-day, and probably not once in the course of the week. Even when eagles are on the hunt, they do not occasion much general alarm to those animals upon which they prey. The eagle, when "towering in her pride of place," certainly commands in vision, and can command in power of destruction, a very wide horizon; but still her command, even at this time, is one of peace and general safety; and as hawks and buzzards and harriers, which are really far more destructive, especially of moor game, than eagles, are not very fond of beating the bushes if there is an eagle above them in the sky, it is doubtful whether, upon the whole, the golden eagle may not partake more of the character of a preserver than of that of a destroyer. Even when she has singled out her prey, and is about to stoop at it, the fluttering wings, as she winds herself up to the bent of her power, and the loud note with which she begins her descent, all tend to warn the rest of the animals, so that they lie close; the eagle devours the prey in silence, and she does not stoop again on the same ground during the same day. The consideration of these points is of some consequence in those places where the remains of this truly splendid race of birds are still to be found; and, as an eagle upon a mountain rock, or in the mountain sky, is certainly worth something, it would be a matter of at least some importance to ascertain whether the evil of them so far overbalances the good, as to warrant a price being set upon their heads, or rather upon their feet, in most places where there is a vestige of them left, and sheep have been introduced.

So far as our personal experience goes—and we have seen a good deal of those places in our own country where the golden eagle is still to be met with in straggling pairs, inhabiting some of the more wild and rocky places—our judgment, founded upon this experience, is in favour of the eagle. Even if these birds did occasionally capture a lamb, or descend upon a sheep that had stuck fast in the mire, and must have perished there, eagle or no eagle, there are surely other pleasures for mankind besides the mere fact of eating sheep! and as these birds never invade those places of which man has properly taken real and practical possession by cultivating them, it is not easy to see upon what well-grounded plea, either in nature or in the economy of art, man should invade the eagle's country in the not very reputable character of a merely wanton destroyer. It really does not

appear that man has established any title to seek and destroy the eagle upon the ledge of the mountain rock, unless he has built his own dwelling there; and if he so builds, the eagle will confess the superiority of this his legitimate title, and go away of her own accord; but, till then, it really appears that there is a natural right on the part of the eagle, and that to disturb her is wanton cruelty, and manifest injustice.

We strongly suspect too, that the "informations" laid against the eagles come chiefly, if not solely, from that most fertile of all sources of error and absurdity, "book-learning." The stories about eagles which are repeated again and again, are, no doubt, terrible enough, and likely enough to mislead and prejudice the minds of the ignorant; but they are not the more likely to be true upon this account, and by far the greater number of them bear internal evidence that neither the manufacturers nor any of the successive retail dealers knew any thing about the habits of eagles, or had ever by chance seen one in wild nature, nor could they, had they seen one in the sky, have distinguished it from a heron, or even a wild-goose.

We have discussed the subject of the mischief done by eagles with very intelligent sheep farmers in the neighbourhood of their eyries, that is, as near as a house or habitation can be to a golden eagle's nest; and though the general opinion among these parties was, that eagles, as a race of destroyers and pests, ought to be exterminated at all times, and by every means—that, in short, the killing of an eagle was almost, if not altogether, as meritorious a deed as the saving of a human life. In proof of this fact, the bell pulls, and in some cases the handles of whips, were finished off with eagles' feet, in testimony of the victories which had been gained over them. When, however, we came to the main point of the case, the real harm which had been done by the eagles, they were invariably obliged to have recourse to other times, and other places, for their instances. "No great harm had been done by the eagles since they had possession, neither did they recollect of any which had happened just in that part of the country; but they had been told, and they had no doubt of the truth, that very serious damage had been done half a century ago, and even in times much more recent, at some place thirty or forty miles distant." No matter for the place—this was the invariable account: the eagles of the one side of the great ridge of the Grampians, or of any of the other ridges, less extended but hardly less elevated, and, generally speaking, much more wild and picturesque, always did their mischief on the other side. For instance, the eagles of the glens of the Tay, the Illa, and all the southward running rivers, were always troublesome fellows to the people of Badenoch; while the eagles of Strathspey hewed down the lambs and muttons in the south as if the birds had been Samson and the flocks Philistines; and so marvellous were the tales that we were often put in mind, that not the eagles but the narrators might probably have found and armed themselves with the weapon of the puissant son of Manoa.

What may be done by those eagles which have a portion of the character of the vulture in them, which come near the banks of the streams and shores of the creeks, and approach more closely to the habitations of man, we have not the means of ascertaining from personal observation; but it is very unlikely that, under any state of things, the golden eagle can, or could be very injurious to man. As for killing lambs, the eagles do not come so far down, excepting at a rare and

random dasn, on the places where the lambs are dropped; and, if any breeder of sheep should be unwise enough to send his brood ewes to the upper glens and summits near the dwelling of the eagles, he would stand in need of no eagles to kill the greater part both of the young and the dams, though crows and ravens to clear off the carrion might be of service to him.

Golden eagles are now unknown as resident birds in a wild state in England. In Scotland they are confined to some of the wildest spots, invariably inland. It is, usually said, that there are some in the craggy mountains near the lakes of Killarney, in the county of Kerry, in Ireland; though, from the accounts which we have heard of their preying in the lake (at least occasionally), we should be inclined to believe that, they belong to another species which is far more common than the golden eagle, which does haunt near the waters, and occasionally fish; and the characters of which may be supposed to vary a little, according as the nature of its pastures leads it to be more of a land preyer, or more aquatic. Golden eagles are also found in the wild and rocky places among most of the higher mountains on the continent of Europe, though we believe that, in those localities, they are not numerous; and they do not range far from those rocks in which their eyries are placed.

Golden eagles are subject to considerable variations of colour, both with age in the individual, and in different individuals; and they are also subject to considerable variations in size; the male bird being smaller than the female, as is usual among birds of prey, and individuals of both sexes varying a good deal in size from each other, even when they are full-grown. These differences of size are understood to arise chiefly from the different supplies of food which they get while they are in the nest, and up to the time when they attain their full size. When young they are exceedingly voracious, as might be supposed of birds who have to elaborate such well sinewed frames and such firm feathers. The parent birds, true to the adaptation of necessity and supply, which runs so conspicuously through all nature, labour most industriously to obtain the requisite quantity; and where prey is abundant, the larder of an eagle is sometimes so well stored, as to tempt the cupidity of human plunderers. If, however, the requisite quantity is not to be had, even the strength and the enduring perseverance of an eagle is of no avail, because she can neither cultivate that on which she supports her family, nor entice it within the range of her excursions. This is also the time at which the birds are most discursive and most frequently on the wing, and consequently it is the time at which she stands in most danger of being destroyed by man; therefore the labour of feeding the brood sometimes devolves wholly on the one parent, and this must farther tend to dwarf the size of the brood.

Making allowance for the variations of which we have taken notice, the following are nearly the average external characters of the female golden eagle, which is the more powerful bird, and therefore the typical one, at that age when the colours expressive of youth have disappeared, and those of old age have not come on:—Tip of the bill and the claws black; basal part of the bill bluish; naked skin or cere at the base of the bill, and toes, which are the only naked parts of the feet, yellow; irides of the eyes bright orange brown, inclining to yellow; crown of the head and

nape of the neck bright orange brown; sometimes, in birds which have passed a certain age, margined with white, which becomes broader as age increases. The feathers on the neck narrow, pointed, and very distinct, bristling out from each other when the bird is in a state of excitement; chin and throat rich dark brown, passing gradually into pale reddish brown on the under part, in which it terminates in the vent feathers, and feathers on the tarsi, the latter being slender and very much produced; upper part deep orange brown, margin rather paler, which gives a bold relief to the individual feathers; coverts of the wings nearly the same; secondary quills clouded with various shades of brown; and primary quills black. Tail purplish brown, barred across with blackish brown, and having a broad line of the same across the extremity. The feathers are all remarkable for the firmness of their texture, and their profusion in the eagle feather, which gives them something of the same appearance as if they were imbricated scales. For some of the particulars of the beak, the claws, the bones, and the adaptation for flight, see the article BIRD.

In the young birds, the irides are more brown, and the brown on the back and wing coverts is deeper, and the margins of the feathers not so distinct or rich in the tint. There are patches of white on the under part; the insides of the thighs are white; the webs of the feathers of the wings have also more or less white on them; and in the first year's plumage, a large portion of the basal part of the tail feathers is white. In this stage of plumage, the young have often been described as a different species, under the name of the "ring-tailed" eagle, though the ring, which is at first little else than the broad brown bar on the end of the tail, might of itself have sufficed to identify the species. As the bird advances to maturity, the white becomes less and less every year, and in the fourth moult it generally disappears, though there may be a few that retain the white of youth partially on the under part and the base of the tail-feathers until the white of age begins to appear. The length of the mature female is usually about three feet, and the extent of the wings between six and seven feet; though specimens of much larger dimensions have been mentioned.

As this bird is highly characteristic of some of the wildest scenes in Britain, and withal very ornamental, we shall close our notice of it by an extract from Mudie's Feathered Tribes of the British Islands:—

"From what I have noticed of their habits, I am inclined to believe, that eagles in general choose those rocks, where, with an elevation and wildness which gives them the seclusion that they seem to like in their retreats, they have the command of a double pasture: one, a hill, which they beat with a lower flight when the weather is dusky, and a lower and richer one, which they beat at a greater elevation when the weather is clear;—at all events, I have seen them on the upper moors flying low on dusky days, and again sailing majestically over the lower and richer valleys when the day was fine.

"The eyrie of those magnificent birds, which is a dwelling as well as a cradle for their broods, is placed on some ledge of the rock, and rarely on a tree, unless where the tangled roots spring from the cliff, and offer a broad space, which can be covered with sticks. The place is, generally, slippery with the refuse of their prey; and when the young are there, it is usually well stored with provisions, which consist

indiscriminately of quadrupeds and birds. The eggs are seldom more than two, though some say that there are occasionally three, and that in such broods there are two females, one of which becomes an "odd eagle" and lives solitary, growing to a very large size, being very ferocious, and dropping addled eggs occasionally on the mountain tops; but the tale wants verification.

"The eagle generally strikes her prey upon the ground, and the stoop is almost instantly fatal to any animal on which she pounces. The mere fall of a body of twelve or even eighteen pounds in weight, from an elevation of 1500 or 2000 feet, would be powerful; but the eagle shoots down with a great initial velocity, and as she delivers the whole of her momentum with the claw, she not only dashes the animal to the earth, but plunges the claw into its body up to the toe, dislocating the spine or breaking the skull of the feebler quadrupeds, such as hares, and the death of grouse and black game, which form a very large portion of the prey, is instantaneous. The view upon which the eagle proceeds must be a steady one, for on the ground she seldom misses her pounce, though she often does when she attempts to hawk on the wing, as her broad wings and forward rush are both unfavourable to turning, so as to follow the motions of the bird. If the prey is small, she has the power of slackening her speed as she descends, so as to temper the ultimate effect to the necessity there is for it, otherwise, strong as she is, she might be injured by the collision with the ground. An unrestrained stoop from her greatest height would be sufficient to dash even an eagle to pieces. If the pounce is not fatal, the clutch instantly follows, in the giving of which the whole weight of the bird—in the utmost excitement, with the head elevated, the neck stiff, the feathers of the head and neck erected, and the wings shivering so as to keep the pressure on the instruments of death—is upon the claws. With small animals, even when they show signs of life after the pounce, the clutch is given with one foot only, and the bird is less excited; but in no case is the prey touched with the beak, or even looked at, until all motion in it has ceased. When the eye has guided the descent, and the talons have taken effect, the office of the eye is at an end, and the work of death is committed to instruments admirably fitted for carrying it into effect. In general the prey is borne off, but in some cases it is devoured on the spot, that taking place, of course, at those times when the bird has only herself to provide for.

"In winter, when her pastures are covered with feet or even with fathoms of snow, the eagle is often for weeks together without food. That may be one of the causes (for all phenomena, whether of birds or any thing else, have causes) why she drives the young not only from the eyrie, but from her haunt generally before the intensity of winter sets in; and it is said, that she drives them lower down the country, where the chances of food are more numerous.

"Thus the instinct which we are apt to regard as an unkind one is the very best adapted for the preservation of all; and the eagle is, in her way, just as tender a mother as any other animal. As it is necessary for her brood to grow fast and get strong before the inclement season sets in, she is most indefatigable and most successful in supplying them with food, and equally daring in the defence of them against any intruders that may have the temerity to invade an

eagle's nest; and when they are so far matured that they can kill prey for themselves, she drives them down where prey is more easily obtained, while she herself remains to brave the winter at the very throne of its dominion. Herein we may see a beautiful instance of that balance and reaction which can be traced through all the works and operations of nature. Populating and cultivating narrow the bounds and diminish the number of eagles, but as there is a constant tendency in the eagles to spread and extend their territory and their numbers, that tendency instantly acts upon the withdrawal of the restraint; so that when the eagle becomes necessary in order to maintain the balances of races, and the perfection of the whole of nature, she returns by as unerring a law of nature as that which guides her to her prey.

"Her strength of endurance also enables her to keep her footing and preserve her existence, under circumstances to which the powers and the life of almost any other animal would be obliged to yield. The same elastic ligament, which, of its own nature, and without effort from the bird, compresses her toes in clutching, enables her to cling to the pinnacle of the rock, and to cling the more firmly the ruder the blast. The claws are not used in those cases, as that would injure their points, and unfit them for their proper functions; but the pads and tubercles hold on upon places where the foot of all else would give way; and the eagle sits with closed wings and close plumage, as if part of the rock itself, while the wind roars and the snow drives, tearing the bushes from their roots, sending them rolling over the precipices, and literally scourging the wilderness with ruin. The strength of the hill ox, the fleetness of the mountain deer, and the resources of the mountain traveller, are often unavailing; and when the storm breaks, the signal of the raven and the crow points out the place of their bones; but the bones of the eagle are not thus given by nature to be tugged at by ignoble birds. Queen of the tempest, she rides as secure, amid its fury, as when, on a cloudless and breezeless day, she floats down the valley with easy and almost motionless wing."

We may remark that, notwithstanding the reputation which this celebrated species long has had for being an unreclaimable tenant of the wilds, it is by no means unsusceptible of kindly treatment, and that, if taken young and duly fed, it may be gradually brought to familiarity and even to playfulness. But though this may be done, as probably every animal, whether of the land, the air, or the waters, may be familiarised by feeding, one does not exactly see the use of it; and the bird is certainly not only out of its element, but out of its proper use in nature, in any other place than on its native rocks and in its favourite skies.

The young of this species, while they have the white on the basal part of the tail, partially on the under part of the body, and on the insides of the thighs, and also the brown on the upper part less broken by the yellowish margins of the feathers, are very apt to range into places where the old ones are never seen; and as they sometimes take up their abode there, and build nests and breed, while still in the young plumage, we need be little surprised that they should have been so generally and so long looked upon as a separate species, and described and figured as the "common eagle." The more judicious naturalists were always of opinion that they were the

same species; and recently the fact has been demonstrated by Selberg.

THE IMPERIAL EAGLE (*A. imperialis*). This is a large and powerful bird, though not so compact in its form, or perhaps so strong in proportion to its size, as the golden eagle. Still it is a long-winged eagle and a mountaineer, and probably approaches nearer in all its habits to the golden eagle than any other of the race. They are, however, easily distinguished from each other, both by the form of the body and the colour. The imperial eagle is proportionally shorter in the body, and thicker, bearing nearly the same relation to the others that the hawks do to the falcons; and being altogether a bird of more southerly climates, and probably less enduring habits. The chief distinctions in colour are: the nostrils transverse, a large patch of white on each shoulder; the tail black, barred and waved with greyish, and the ground colour of the female brownish yellow, rather pale, and broken by brown spots; the crown of the head and the nape are furnished with pointed feathers of a dull rust brown colour margined with lighter. The under part of the belly is a yellowish rust colour, and the whole plumage apparently less firm in its texture and certainly less decided in its colours. The white on the scapulars, and the black and grey tail, instead of one of different shades of brown, always suffice to distinguish this bird from the golden eagle, even when that bird is immature, ranging the country in quest of a mate and a home, and being the ring-tail of British describers, and the common eagle (*l'aigle commun*) of the French, of Buffon, and even of Cuvier.

The imperial eagle is unknown in the British islands, or in the mountains and woods of western Europe; neither is it very abundant even in the Alps, especially on the northern declivities of those mountains. In the eastern Alps, in Hungary, in Dalmatia, and so onward through Greece and Turkey, it is by no means rare; and although its localities have not been so clearly traced in Asia, it is probably to be met with in all the wooded mountains of the western and central parts of that continent, from Caucasus southward, and eastward as far as the Himalaya. It is also found in Egypt and in Barbary, though it probably does not extend southward across the desert of Sahara, the eagle of Guinea being apparently a different species.

Its habits are described as being a little different from those of the golden eagle. Though found more frequently in elevated places, it is not so decidedly a bird of the mountain cliffs as the other; neither does it beat for its prey upon the naked pastures, or at such a height in the air. The wooded hills are its most usual haunts, though, from the length of its wings, it is of course not a preyer in the close forests. The nest is constructed indiscriminately on the ledges of woodland rocks, and in lofty trees, though the latter are preferred where they are equally well situated for the pastures. The eggs are three or four in number, and of a dull white colour. The voice of this species is represented as being more loud and clear than that of any of the other eagles, owing, as is said, to the more compact structure of the trachea.

From the abundance of this species in Greece, and in the mountainous parts of Italy, especially Naples and the island of Sicily, it is highly probable that this, and not the golden eagle, is "the bird of Jove," as fabled by the ancients; and certainly the representations which have come down to us from the Greeks

and Romans have the greatest resemblance to this species. It appears indeed to be the eagle of painters and sculptors all over Europe, and even in those parts of it where the bird, in a state of nature, is altogether unknown. Hence, in a historical point of view, the imperial eagle is rather an interesting bird. As these birds come into places which are rich at certain seasons, and in which the greater abundance and variety of animals probably meet with more casualties than they do in those colder climates, for the endurance of which the golden eagle is so well fitted, it is probable that they partake a little of the vulture character, and help to clear away the carcasses of animals, in the death of which they have little or no concern. Their young being rather more numerous than those of the golden eagle, and equally voracious during the period of their growth, the old birds have no small labour in finding the necessary supply of food; and the time when they have young may be known by their frequent appearance on the wing, and the diligence with which they range over the pastures. These pastures are, in general, more abundantly stocked than the pastures of the golden eagle; but as the vegetation is more rank in the early part of the season, the prey is not so easily discerned from a height in the sky. They do not, indeed, fly so high as the others; but they have the eagle habit of stooping on their prey, and not chasing it on the wing, or beating the bushes for it on low flight.

THE LITTLE, OR SPOTTED EAGLE—*A. maculata*. This is a much smaller species than either the golden or the imperial eagle, being one-third less in the linear dimensions, and estimating animals as the cubes of these, which is the proper way of comparing their volumes, if not their strength, the little eagle is rather less than equal to half the others in volume. It appears to form a sort of connecting link between the eagles and buzzards; and like the latter, and different from the former, it has the tarsi elongated and slender. Indeed, though the more eminent of the authorities class it with the eagles, it appears to be more of a buzzard in the greater number of its characters.

It is a native of the mountain forests of the southern parts of Europe, and very common in or near the woods of the Apennines; but it is rarely seen in the central countries, and never in the north. It is also found distributed over great part of Africa, and bears so much resemblance to the little eagle of Senegal, and that of the Cape, and even to some which are found in the south-eastern peninsulas of Asia, and in the Oriental islands, that a particular description of them does not appear to be necessary. It appears, indeed, that eagles are peculiarly subject to climatal differences of colour, as even the golden eagle, which is probably the most local of the whole, is sometimes spotted with white.

As this species is less powerful and also less energetic than the larger land eagles, its prey is of a more humble description. It does, of course, catch rabbits and little birds, and occasionally a duck, especially a young one; but to these it adds mice, reptiles, and some of the larger species of insects. The plumage of the mature bird is brown, varying in depth of tint both in the individual, with age, and in the sexes.—The tail is dusky or blackish, with bars of paler, and the extremity reddish. The under parts, and lower coverts of the tail, are bright brown; the cere and feet yellow, and the bill and claws black. The immature birds have the coverts of the wings, and part of

the scapulars marked with large spots of greyish white. They have similar spots on the secondary quills, and the upper parts of the wings are marked with smaller yellowish spots. It is when in this immature state that it is called the spotted eagle.

THE WEDGE-TAILED EAGLE—*A. fucosa*. Why this species should be called *fucosa*, or "painted," it is not easy to say, unless it be on account of the depth of its colour; for the tints are any thing but rich. Its general colour is a dull brownish black, with a reddish tinge on the breast. It is a native of New Holland, and has not been found out of that country. Its form, its air, and its linear dimensions, bear no inconsiderable resemblance to those of the golden eagle; but it is more slender and feeble, and the wedge-shaped tail, different from the broad fan-tail of the golden eagle, indicates a very considerable difference of habit. The broad fan-tail indicates a bird which has the habit of frequent ascent and descent, which is that of the golden eagle, and indeed of all birds that have the tail of that form, whether they be birds of high flight, like the eagle, or only birds that leap up to their perches, or rise to avoid enemies upon the ground. The wedge-shaped tail, again, almost invariably indicates a bird which has to make its way through some sort of tanglement, the boughs and branches of trees, bushes, or tall herbage of some kind. The species of eagle under notice, of which a specimen has been at the gardens of the Zoological Society of London, is described as feeding on the emeu, and the young of the kangaroo; but in what manner it captures its prey, whether by stooping, like the eagles properly so called, by pouncing on them, by level flight, from caves, or by any other method, has not been said, neither have we any correct information respecting the nest-building or the other habits of the bird.

These are the principal species of eagles, properly so called, that inhabit the land, and for the most part feed upon warm-blooded animals only. The probability is, that there are more in those places, the mountains and forests of which have not yet been explored. But the forests of tropical countries are not proper localities for the typical eagles; they are too rich and tangled for allowing these birds to act; and, therefore, we may rather expect to find in them vultures, or those short-winged fishing eagles which feed readily upon carrion, and otherwise appear to have not a little of the vulture in their composition.

All those land eagles have the under or concave sides of the toes of a more trenchant and tearing character than those that fish, the claws of the latter having more of the character of prehensile hooks. No doubt they can inflict very severe wounds; and as their points are generally finer, they can penetrate the body of an animal with the exertion of less force. The toes are also more adapted for clutching, so as to take a hold, and lift and carry a weight; and the tarsi are bare of feathers and covered with reticulated scales, like those of the wading birds.

These differences of structure are very well adapted to their differences of habit, so much so that if we be well acquainted with the habits of any one of either of the subdivisions, we can have no difficulty in judging of the leading habit of any other from the structure. The land eagles do not require the very fine points to their claws, and in the case of those who tenant the rocks, the fine points would be apt to be broken or worn, notwithstanding that they are not

used directly on the surface of the stone. Their prey is on the ground when they penetrate it with their talons; and thus they act against a solid resistance; and as this compensates for the comparative bluntness of the claw, and the blunted claw inflicts by much the more severe and painful wound, it is the best one for their habits. We find a parallel case in the teeth of the lion, which, though large and powerful, are comparatively blunt. But the fishing eagles have to strike their finny prey against the water only, which has no cohesion as the earth has, and therefore, it gives way like an elastic spring; and, if the points of the claws were not very sharp, they would not penetrate the skin of the fish. So, also, if they were furrowed and grooved like the talons of the land eagles, which use theirs in killing the prey, and not in clutching it for the mere purpose of lifting, they would tear and lacerate, and, in the case of a heavy fish, cut their way out of its substance. By being round and smooth on their under sides, the talons of the fishing eagles have no tendency to do this. The articulations of the toes are also admirably fitted for retaining a powerful hold. They contract much more completely in the distal joints than those of the land eagles; they, in fact, bend till the point of the claw is on the same level with the root, and thus every single claw lifts like a perfect hook, while the connexion of the foot keeps them all in their places. The strain of the clutching is at the same time not wholly upon the muscles which contract the toes, for the bird does not dangle the fish with the toes, at full length, but binds all the joints, which throws part of the strain upon the ligament, and the rest of it is parted among all the muscles of the leg.

There are considerable differences of structure and habit among the fishing eagles; some of them approach the land eagles in many of their characters; and the ones that do so are long-winged, and prey upon land animals, as well as upon the produce of the sea; others, which are still longer winged, are more exclusively aquatic, and they have the feet most approaching to that form which we have described as a proper fishing foot; and others, again, have the wings shorter and broader, living more in the vicinity of those waters the banks of which are thickly covered with trees; and they partake in some measure of the habits of the vultures, and also of the hawk,—they eat carrion and any offal that comes in their way, and they also chase birds on the wing, and strike them in the air, which is not a habit of the true or typical eagles. It is not, perhaps, very easy to follow accurately the distribution of these; and many of them, like those who inhabit the dense forests, are but imperfectly known, but we shall begin with those that are most nearly allied to the land eagles.

THE ASH-COLOURED EAGLE (*A. cinerea*). This species is common on many places of all the shores of Britain, and hence it has various names. In many places it is "the eagle" simply, because it is the only one which makes its appearance. It is also often called the "white-tailed eagle," from the colour of its tail; in some places it is "the bog eagle;" and in those parts of the lowlands of Scotland where it is popularly known, it is called the "erne." The name which we have given it is as little objectionable as any; and it harmonises with the only other true eagle, native in Britain, which gets its name from the rich yellowish brown on the margins of the feathers.

As is the case with the young of the golden eagle.

the young of this has often been described as a different species. The cause of this appears to have been of the same nature with that which led to a similar mistake in the case of the golden eagle. The young birds and the old ones are, as in that species, different in colour; and about the same length of time elapses before the perfect mature plumage is assumed. The young are much more discursive along the shores than the old birds; and as the probability is that they do not pair till they have passed two winters, they may be found on the shores when a year old, in the breeding time, when the old ones, which prefer trees to rocks for their nesting places, are then more inland. The young, however, before they have acquired their perfectly mature plumage, do pair, and have at least one brood, and in all probability two. Thus the birds in the one plumage appear when the others do not; they appear more on the shores, and there are pairs and broods among birds in both plumages. Therefore, these are as satisfactory proofs as can be obtained in most cases that there are really two distinct species; and the fact would not have been called in question, if it had not been ascertained by direct observation of the change and the age at which it takes place, that these two apparent species are one and the same. The young was the "sea eagle" of British describers, and called *Aquila ossifraga*, or the "bone-breaking eagle," while the adult was the "cinereous eagle" and the "white-tailed eagle."

This species is as large as the golden eagle, or probably a little larger; but its form is not so compact, it does not appear so firmly knit, and its expression is by no means so lively or intelligent. Still it is a very powerful bird, and if we looked only at the size of its destructive weapons, we would be apt to conclude that it were the more formidable bird of the two. Both its bill and its talons are larger than those of the golden eagle, and the talons are more crooked and sharper at the points. But when we come to examine both birds narrowly, we find that there are indications of inferiority about the present species. The beak is yellow, and, though larger in size, it seems softer and weaker than that of the other, and not so firmly based on the bones of the head. Its cutting edges are also not so decidedly formed. It is straight for a greater length at the base, and the toothed wavings, which enable the beak of the other to take so firm a hold in tearing, are nearly obliterated. The beak of the one resembles a smaller instrument of steel, that of the other a larger instrument of soft iron. The claws too, though better clutching and retaining instruments, are not of so mangling a character. They are a little flattened on their under sides; but they are without the prominent ridges which enable the others to act with such effect.

But, after all, this eagle is a very powerful bird and well armed for the work of destruction. As compared with the golden eagle, it follows the usual law of the difference of birds which are wholly or partially marine, and birds which are exclusively inland. It is found inhabiting much farther to the north, and it is more discursive, and ranges more with the seasons. It is found in Iceland, in the Faroe Isles, in Shetland, in the Orkneys, in the Western Isles, and on the wild and rocky shores of the west of Scotland generally. It sometimes ranges into England, but it is not numerous so far to the south. In summer it haunts and hovers over the fresh water pools and morasses, where water fowl breed in great numbers, and is very de-

structive of them; and it also attacks the smaller quadrupeds, and, as is said, even sheep and deer, especially in the early part of the season when they are sickly and weak.

As these birds are of strong wing, and capable of enduring hunger for a long time, they extend their winter excursions often to a great distance from their breeding places. Those which appear in England, and although they are not numerous, they are found in the most southerly parts as winter visitants, are understood to leave the north when the sea is too stormy for them, and they are frozen out on the northern lands. It has sometimes been said, that the appearance of these eagles in greater numbers than usual is accompanied by more than the usual supply of wild fowl.

They retire a little toward the north in the breeding time. Those which breed in the far north countries build in the rocks, choosing the most elevated and inaccessible places; and indeed they have no alternative, as there are no trees in those countries. In places where there are trees in wild and secluded situations, either near the sea or the inland waters and marshes, though never very far inland, they give the preference to this. It is not understood that they keep so constantly to the same eyrie, or even to the same locality, as the golden eagles. There is one particular mentioned with regard to their broods and their apparent numbers, in which they agree with many of the larger sea birds which build on the cliffs. Their eggs are few in proportion to their apparent numbers, being never more than two, and often only one.

The general colour of these birds in the young state, or before they have acquired the mature plumage, is dark brown, with the margins of the feathers of a lighter tint. On the lesser coverts, the scapulars, and the throat, these margins are very pale, approaching to a reddish straw colour. The under part at this age is spotted, and among the varied spottings there are always some patches of white. The tail is dark brown, as deep in the tint at the extremity as the bar on the tail of the golden eagle; but the other parts are much mottled with lighter brown. The bill at this age is of a leaden grey or bluish colour, but very different in tint from that of the golden eagle. As the bird approaches maturity, the feathers on the head become paler in their tint, and the bill alters to a straw colour; the cere and irides acquire a tinge of red; and the pale margins of the feathers on the upper parts and the throat fade off, rendering the brown more uniform and unbroken. The mottlings also disappear from the under part of the bird, which becomes a deeper brown than the upper. The most remarkable change, however, is in the tail and tail-coverts, which, from being the darkest parts of the bird in the early plumage, become pure white in maturity.

This is the species of which so many marvels are told by the people of the north, about its carrying away children, and an endless number of other adventures. But those northern people, who have been always obliged to have recourse to tales of wonder, in order to help them through the tedious darkness of their long winter nights, have thrown an air of romance around almost everything that is connected with their countries, whether in natural history or in any thing else; and as this eagle is one of the most conspicuous of their native birds, we

need not wonder that it has come in for its full share of the exaggerations; yet, in spite of the exaggerations, it is a bird of no small interest to all who love nature, and wish to study its phenomena and economy in the wildest places.

The fishing of this eagle is not so habitual, neither is it performed in so fine a style, as that of another and smaller species, afterwards to be described; but still it does occasionally fish, and that in the sea, against the rocky and precipitous shores, which it prefers, as it never comes upon the flat ones unless they are in the neighbourhood of marshes, to which it can make incursions inland. For its permanent residence such places must be lonely, and far from those which are thickly inhabited by mankind, so that the sea-eagle, though much more frequently seen than the golden eagle of the mountains, is still, like that, a bird of wild nature in its general habits. Though not unknown upon any of the wild or cliffy shores of England, where they partake of that lonely character in which it delights, this bird may be considered as more abundant on the western and northern shores of Scotland than on any other of those of Britain. There it may be met with all along the deep bays, or lakes, as they are called, which run far into the land, and are peculiarly wild in their character; and perhaps there is no place in which it is more common than about Loch Carron and Loch Roan, and the great inland lake Loch Murce. The latter is an exceedingly romantic spot. The cliffs are bold and rugged, and there are trees, some old hollow ones, of large dimensions, on the islets in the loch, or the more romantic places in its vicinity. Upon these, or in the bushes, which are found higher up, chequering the grey of the cliffs with rich green foliage in the summer months, these eagles form their nests; and, as, in that situation, they have both sea and land within the easy range of their wing, they appear to be quite in their element. Their appearance is indeed so common, and their size, and the style of their flight, so conspicuous, that they add not a little to the effect of scenery naturally of the wildest character.

The breadth of the island at that part is not more than the range of a sea-eagle's flight, and thus they are found on the rocky shore of the east about the Ord of Caithness, and also along the whole of the north of Sutherland, as well as on the west. The northern shore there, from Cape Rath eastward, along the whole of Sutherland and great part of Caithness, is as wild as can well be imagined. The current which sweeps through the Pentland Firth alternately to the east and the west, in consequence of its being high water on the one side of the country when it is low water on the other, sweeps the bases of the cliffs with an ever-rolling flood; and, when the north wind blows in its fury, which it does in the latter part of the season, just before the hills have received their winter covering of snow, the roll of the north sea comes in mountains, and breaks in thunder, so that the whole line of the coast is not only, so to speak, worn to the bones of the mountains, but these are honeycombed into innumerable caves, many of them reaching to a great distance below ground, and some of them perforated at their landward extremities by large apertures to the day, up through which the dashing water spouts in splendid jets, sometimes raising large stones to the height of a good many feet, from which they fall with tremendous crashes back

again upon the aperture. The resistance of the weight of the stone, if a large one, condenses the air which the surge drives before it into the cavern, till that becomes charged like an air-gun, from which both the stone and the water are literally shot upwards into the air; and when fishes are abundant near the coast, they are apt to lose command of themselves in the turmoil of the waters, and to be flung upon the rocks by those singularly magnificent jets. On such a shore the sea-eagles are quite in their element, and have associates of more aquatic character to assist them in filling up the picture. Gannets, and skrags, and cormorants, plunging head-long into the waters, divers driving about through the restless surges, gulls wheeling and wailing on the wing, and ever and anon dipping down to catch those smaller fishes which come near to the surface, and skuas driving at the gulls, making them disgorge their booty, and catching it ere it falls into the sea. Meanwhile, the sea-eagle sits on the rock, eyeing the tumult of nature, but always now and then making a clutch at the waters for her share of the booty.

Nor in the more tranquil season of the year is the prey of the eagle less abundant, though she then finds it of different quality, and in a different situation. The short summer in these northerly places is as much a time of repose as the change from summer to winter is one of turbulence; and as there is little night, and no absolute darkness, the situation is peculiarly favourable for the breeding of those wading and swimming birds which are twilight feeders. Accordingly, the morasses, and the grassy and rusny margins of the ponds and lakes, are full of the nests of these birds, and during the time that they are there, the sea-eagle fares as well as a fowler as she does as a fisher at other times of the year.

THE WHITE-HEADED EAGLE (*Aquila leucocephalus*). This is an American species, agreeing in its general habits with the white-tailed eagle of Europe, but differing from it in its appearance, and especially in the position of the white, upon which the common names of both are founded. It is usually said that this species is occasionally, or rather not unfrequently, seen in the north of Europe, and it may have been observed there, though there is at least a possibility that the osprey, which is common to both countries, and much more frequently seen on the shores, even in America, than the white-headed eagle, may have been mistaken for it. They both fish, though the osprey is by far the more habitual and the finer fisher of the two, has its plumage of a much more aquatic character, and dashes far more fearlessly into the water. The old osprey, however, has the head white, so white that it has got the popular name of the "bald" buzzard, just as the species under notice has got that of the "bald" eagle. On close inspection of the birds, when they are seen together in an aviary or a museum, it is very easy to distinguish this eagle from the osprey, by the size, the shape, the plumage, and the general air and character. But when we come to examine the larger birds of prey in wild nature, we find our aviary and museum knowledge of much less use to us than we could wish, or even believe, till we actually make the trial. We cannot come so near the birds as that we can be sure of the details of appearance upon which the specific descriptions are usually formed. We are not very good judges, even of size, when we change very much the characters of our locality; and one who, for the first

time, sees a large bird of prey floating high over bold and rifted cliffs, the peaks of which shoot up to some thousand or fifteen hundred feet in height, as is not unfrequently the case on those shores of Europe which the white-headed eagle has been said to frequent, can form no very accurate estimate of its size. In all such cases, whatever is seen on or over the top of the cliffs by a spectator below, "borrows of the cliff," and is larger to the fancy than it would be in fact if we had it on the level ground, and could measure it with a line.

White-headed Eagle.

As this bird is certainly much more characteristic of North America than of any other part of the world, and, as it is there a bird of the greatest interest, we should be doing it injustice if we attempted to describe it in any other language than that of Wilson:—"This distinguished bird," says this equally distinguished naturalist, "as he is the most beautiful of his tribe in this part of the world, and the adopted emblem of our country, is entitled to particular notice. The celebrated cataract of Niagara is a noted place of resort for the bald eagle, as well on account of the fish procured there, as for the numerous carcasses of squirrels, deer, bears, and various other animals that, in their attempts to cross the river above the Falls, have been dragged into the current, and precipitated down that tremendous gulf, where, among the rocks that bound the rapids below, they furnish a rich repast for the vulture, the raven, and the bald eagle, the subject of the present account. Formed by nature for braving the severest cold; feeding equally on the produce of the sea, and of the land; possessing powers of flight capable of outstripping even the tempests themselves; unawed by any thing but man; and, from the ethereal heights to which it soars, looking abroad at one glance, on an immeasurable expanse of forests, fields, lakes, and ocean, deep below him, he appears indifferent to the little localities of change of seasons; as in a few minutes he can pass from summer to winter, from the lower to the higher regions of the atmosphere, the abode of eternal cold, and from thence descend, at will, to the torrid or the arctic regions of the earth. He is, therefore, found at all seasons in the countries

he inhabits; but prefers such places as have been mentioned above, from the great partiality he has for fish.

"In procuring these, he displays in a very singular manner the genius and energy of his character, which is fierce, contemplative, daring, and tyrannical; attributes not exerted but on particular occasions, but, when put forth, overpowering all opposition. Elevated on the high dead limb of some gigantic tree, that commands a wide view of the neighbouring shore, and ocean, he seems calmly to contemplate the motions of the various feathered tribes that pursue their busy avocations below; the snow white gulls slowly winnowing the air; the busy *tringæ* coursing along the sands; trains of ducks streaming over the surface; silent and watchful cranes, intent and wading; clamorous crows; and all the winged multitudes that subsist by the bounty of this vast liquid magazine of nature. High over all these hovers one whose action instantly arrests his whole attention. By his wide curvature of wing, and sudden suspension in air, he knows him to be the fish hawk, settling over some devoted victim of the deep. His eye kindles at the sight, and, balancing himself, with half-opened wings, on the branch, he watches the result. Down, rapid as an arrow from heaven, descends the distant object of his attention, the roar of its wings reaching the ear as it disappears in the deep, making the surges foam around! At this moment, the eager looks of the eagle are all ardour; and, levelling his neck for flight, he sees the fish hawk once more emerge, struggling with his prey, and mounting in the air with screams of exultation. This is the signal for our hero, who, launching in the air, instantly gives chase, and soon gains on the fish hawk; each exerts his utmost to mount above the other, displaying in these rencontres the most elegant and sublime aerial evolutions. The unencumbered eagle rapidly advances, and is just on the point of reaching his opponent, when, with a sudden scream, probably of despair and honest execration, the latter drops his fish: the eagle, poising himself for a moment, as if to take a more certain aim, descends like a whirlwind, snatches it in his grasp as it reaches the water, and bears his ill-gotten booty silently away to the woods.

"These predatory attacks and defensive manoeuvres of the eagle and the fish hawk, are matters of daily observation along the whole of our sea board, from Georgia to New England, and frequently excite great interest in the spectators. Sympathy, however, on this, as on most other occasions, generally sides with the honest and laborious sufferer, in opposition to the attacks of power, injustice, and rapacity, qualities for which our hero is so generally notorious, and which, in his superior, *man*, are certainly detestable. As for the feelings of the poor fish, they seem altogether out of the question.

"When driven, as he sometimes is, by the combined courage and perseverance of the fish hawks from their neighbourhood, and forced to hunt for himself, he retires more inland, in search of young pigs, of which he destroys great numbers. In the lower parts of Virginia and North Carolina, where the inhabitants raise vast herds of those animals, complaints of this kind are very general against him. He also destroys young lambs in the early part of spring; and will sometimes attack old sickly sheep, aiming furiously at their eyes.

"In corroboration of the remarks I have myself made on the manners of the bald eagle, many accounts

have reached me from various persons of respectability, living on or near our sea coast. The substance of all these I shall endeavour to incorporate with the present account.

"Mr. John L. Gardiner, who resides on an island of three thousand acres, about three miles from the eastern point of Long Island, from which it is separated by Gardiner's Bay, and who has consequently many opportunities of observing the habits of these birds, has favoured me with a number of interesting particulars on this subject, for which I beg leave thus publicly to return my grateful acknowledgment.

"The bald eagles," says this gentleman, "remain on this island during the whole winter. They can be most easily discovered on evenings by their loud snoring while asleep on high oak trees; and, when awake, their hearing seems to be nearly as good as their sight. I think I mentioned to you, that I had myself seen one flying with a lamb ten days old, and which it dropped on the ground from about ten or twelve feet high. The struggling of the lamb, more than its weight, prevented its carrying it away. My running, hallooing, and being very near, might prevent its completing its design. It had broke the back in the act of seizing it; and I was under the necessity of killing it outright to prevent its misery. The lamb's dam seemed astonished to see its innocent offspring borne off into the air by a bird.

"I was lately told," continues Mr. Gardiner, "by a man of truth, that he saw an eagle rob a hawk of its fish, and the hawk seemed so enraged as to fly down at the eagle, while the eagle very deliberately in the air, threw himself partly over on his back, and, while he grasped with one foot the fish, extended the other to threaten or seize the hawk. I have known several hawks unite to attack the eagle, but never knew a single one to do it. The eagle seems to regard the hawks as the hawks do the king-birds, only as teasing troublesome fellows."

"From the same intrepid and obliging friend, I lately received a well-preserved skin of the bald eagle, which, from its appearance, and the note that accompanied it, seems to have belonged to a very formidable individual. 'It was shot,' says Mr. Gardiner, 'last winter, on this island, and weighed thirteen pounds, measured three feet in length, and seven from tip to tip of the expanded wings; was extremely fierce looking; though wounded, would turn his back to no one; fastened his claws into the head of a dog, and was with difficulty disengaged. I have rode on horseback within five or six rods of one, who, by his bold demeanour, raising his feathers, &c., seemed willing to dispute the ground with its owner. The crop of the present was full of mutton, from my part blood Merinos; and his intestines contained feathers, which he probably devoured with a duck or winter gull, as I observed an entire foot and leg of some water fowl. I had two killed previous to this, which weighed ten pounds avoirdupois each.'

"The intrepidity of character, mentioned above, may be farther illustrated by the following fact, which occurred a few years ago near Great Egg Harbour, New Jersey. A woman, who happened to be weeding in the garden, had set her child down near, to amuse itself, while she was at work; when a sudden scream from the child alarmed her, and, starting up, she beheld the infant thrown down, and dragged some few feet, and a large bald eagle bearing off a fragment of its frock; which, being the only part seized and

giving way, providentially saved the life of the infant.

"The appetite of the bald eagle, though habituated to long fasting, is of the most voracious and often the most indelicate kind. Fish, when he can obtain them, are preferred to all other fare. Young lambs and pigs are dainty morsels, and made free with on all favourable occasions. Ducks, geese, gulls, and other sea fowl, are also seized with avidity. The most putrid carrion, when nothing better can be had, is acceptable; and the collected groups of gormandizing vultures, on the approach of this dignified personage, instantly disperse, and make way for their master, waiting his departure in sullen silence, and at a respectful distance, on the adjacent trees.

"In one of those partial migrations of tree squirrels that sometimes take place in our western forests, many thousands of them were drowned in attempting to cross the Ohio; and, at a certain place, not far from Wheeling, a prodigious number of their dead bodies were floated to the shore by an eddy. Here the vultures assembled in great force, and had regaled themselves for some time, when a bald eagle made his appearance, and took sole possession of the premises, keeping the whole vultures at their proper distance for several days. He has also been seen navigating the same river on a floating carrion, though scarcely raised above the surface of the water, and tugging at the carcase, regardless of snags, sawyers, planters, or shallows. He sometimes carries his tyranny to great extremes against the vultures. In hard times, when food happens to be scarce, should he accidentally meet with one of these who has its craw crammed with carrion, he attacks it fiercely in the air; the cowardly vulture instantly disgorges, and the delicious contents are snatched up by the eagle before they reach the ground.

"The nest of this species is generally fixed on a very large and lofty tree, often in a swamp or morass, and difficult to be ascended. On some noted tree of this description, often a pine, or cypress, the bald eagle builds, year after year, for a long series of years. When both male and female have been shot from the nest, another pair has soon after taken possession. The nest is large, being added and repaired every season, until it becomes a black, prominent mass, observable at a considerable distance. It is formed of large sticks, sods, earthy rubbish, hay, moss, &c. Many have stated that the female lays first a single egg, and that after having sat upon it some time, she lays another; when the first is hatched, the warmth of that, it is pretended, hatches the other. Whether this be correct or not, I cannot determine; but a very respectable gentleman of Virginia assured me that he saw a large tree cut down, containing the nest of a bald eagle, in which were two young, one of which appeared three times as large as the other. As a proof of their attachment to their young, a person near Norfolk informed me that in clearing a piece of wood on his place, they met with a large dead pine tree, on which was a bald eagle's nest and young. The tree being on fire more than half way up, and the flames rapidly ascending, the parent eagle darted around and among the flames, until her plumage was so much injured, that it was with difficulty she could make her escape, and even then, she several times attempted to return to relieve her offspring.

"No bird provides more abundantly for its young than the bald eagle. Fish are daily carried thither

in numbers, so that they sometimes lie scattered round the tree, and the putrid smell of the nest may be distinguished at the distance of several hundred yards. The young are at first covered with a thick whitish or cream-coloured cottony down; they gradually become of a grey colour as their plumage develops itself, continue of the brown grey until the third year, when the white begins to make its appearance on the head, neck, tail-coverts, and tail; these by the end of the fourth year are completely white, or very slightly tinged with cream; the eye, also, is at first hazel, but gradually brightens into a brilliant straw colour, with the white plumage of the head. Such, indeed, was the gradual progress of this change, witnessed by myself on a very fine specimen brought up by a gentleman, a friend of mine, who, for a considerable time, believed it to be what is usually called the grey eagle, and was much surprised at the gradual metamorphosis. This will account for the circumstance, so frequently observed, of the grey and white-headed eagle being seen together, both being, in fact, the same species, in different stages of colour, according to their difference of age.

"The flight of the bald eagle, when taken into consideration with the ardour and energy of his character, is noble and interesting. Sometimes the human eye can just discern him, like a minute speck, moving in slow curvatures along the face of the heavens, as if reconnoitering the earth at that immense distance. Sometimes he glides along in a direct horizontal line, at a vast height, with expanded and unmoving wings, till he gradually disappears in the distant blue ether. Seen gliding in easy circles over the high shores and mountainous cliffs that tower above the Hudson and Susquehanna, he attracts the eye of the intelligent voyager, and adds great interest to the scenery. At the great cataract of Niagara, already mentioned, there rises from the gulf into which the Falls of the Horse-shoe descends, a stupendous column of smoke, or spray, reaching to the heavens, and moving off in large black clouds, according to the direction of the wind, forming a very striking and majestic appearance. The eagles are here seen sailing about, sometimes losing themselves in this thick column, and again reappearing in another place, with such ease and elegance of motion, as renders the whole truly sublime.—

High o'er the watery uproar, silent seen,  
Sailing sedate in majesty serene,  
Now 'midst the pillar'd spray sublimely lost,  
And now, emerging, down the Rapids tost,  
Glides the bald eagle, gazing, calm and slow,  
O'er all the horrors of the scene below;  
Intent alone to sate himself with blood,  
From the torn victims of the raging flood.

"The white-headed eagle is three feet long, and seven feet in extent; the bill is of a rich yellow; cere the same, slightly tinged with green; mouth flesh-coloured, tip of the tongue, bluish black; the head, chief part of the neck, vent, tail-coverts, and tail, are white in the perfect or old birds of both sexes,—in those under three years of age, these parts are of a grey brown; the rest of the plumage is deep dark brown, each feather tipped with pale brown, lightest on the shoulder of the wing, and darkest towards its extremities. The conformation of the wing is admirably adapted for the support of so large a bird; it measures two feet in breadth on the greater quills, and sixteen inches on the lesser; the longest primaries are twenty inches in length, and upwards of one inch

in circumference where they enter the skin; the broadest secondaries are three inches in breadth across the vane; the scapulars are very large and broad, spreading from the back to the wing, to prevent the air from passing through; another range of broad flat feathers, from three to ten inches in length, also extend from the lower part of the breast to the wing below, for the same purpose; between these lies a deep triangular cavity; the thighs are remarkably thick, strong and muscular, covered with long feathers pointing backwards, usually called the femoral feathers; the legs, which are covered half way below the knee, before, with dark brown downy feathers, are of a rich yellow, the colour of ripe Indian corn; feet the same; claws blue black, very large and strong, particularly the inner ones, which are considerably the largest; soles, very rough and warty; the eye is sunk under a bony, or cartilaginous projection, of a pale yellow colour, and is turned considerably forwards, not standing parallel with the cheeks; the iris is of a bright straw colour, pupil black.

"The male is generally two or three inches shorter than the female; the white on the head, neck, and tail being more tinged with yellowish, and its whole appearance less formidable; the brown plumage is also lighter, and the bird itself less daring than the female,—a circumstance common to almost all birds of prey.

"The bird from which the foregoing description was taken, was shot near Great Egg Harbour, in the month of January. It was in excellent order, and weighed about eleven pounds. Dr. Samuel B. Smith, of this city, obliged me with a minute and careful dissection of it; from whose copious and very interesting notes on the subject, I shall extract such remarks as are suited to the general reader.

"The eagle you sent me for dissection was a beautiful female. It had two expansions of the gullet. The first principally composed of longitudinal bundles of fibre, in which (as the bird is ravenous and without teeth) large portions of unmastered meats are suffered to dissolve before they pass to the lower or proper stomach, which is membranous. I did not receive the bird time enough to ascertain whether any chylefaction was effected by the juices from the vessels of this enlargement of the œsophagus. I think it probable that it also has a regurgitating, or vomiting power, as the bird constantly swallows large quantities of indigestible substances, such as quills, hairs, &c. In this sac of the eagle, I found the quill-feathers of the small white gull; and in the true stomach the tail and some of the breast feathers of the same bird, and the dorsal vertebrae of a large fish. This excited some surprise, until you made me acquainted with the fact of its watching the fish-hawks, and robbing them of their prey. Thus we see, throughout the whole empire of animal life, power is almost always in a state of hostility to justice; and of the Deity only can it be truly said that justice is commensurate with power."

"The eagle has the several auxiliaries to digestion and assimilation in common with man. The liver was unusually large in your specimen. It secretes bile, which stimulates the intestines, prepares the chyle for blood, and by this very secretion of bile (as it is a deeply respiring animal), separates or removes some obnoxious principles from the blood. (See Dr. Rush's admirable lecture on this important viscus in the human subject.) The intestines were also large,

long, convolute, and supplied with numerous lacteal vessels, which differ little from those of man, except in colour, which was transparent. The kidneys were large, and seated on each side the vertebrae, near the anus. They are also destined to secrete some offensive principles from the blood.

"The eggs were small and numerous, and, after a careful examination, I concluded that no sensible increase takes place in them till the *particular* season. This may account for the unusual excitement which prevails in these birds in the sexual intercourse. Why there are so many eggs is a mystery. It is, perhaps, consistent with natural law that everything should be abundant; but, from this bird, it is said no more than two young are hatched in a season, consequently no more eggs are wanted than a sufficiency to produce that effect. Are the eggs numbered originally, and is there no increase of number, but a gradual loss, till all are deposited? If so, the number may correspond to the long life and vigorous health of this noble bird. Why there are but two young in the season is easily explained. Nature has been studiously parsimonious of her physical strength, from whence the tribes of animals incapable to resist derive security and confidence.

"The eagle is said to live to a great age—sixty, eighty, and, as some assert, one hundred years. This circumstance is remarkable, when we consider the seeming intemperate habits of the bird—sometimes fasting, through necessity, for several days, and at other times gorging itself with animal food till its craw swells out the plumage of that part, forming a large protuberance on the breast. This, however, is its natural food, and for these habits its whole organisation is particularly adapted. It has not, like man, invented rich wines, ardent spirits, and a thousand artificial poisons, in the form of soups, sauces, and sweetmeats. Its food is simple, it indulges freely, uses great exercise, breathes the purest air, is healthy, vigorous, and long-lived. The lords of the creation themselves might derive some useful hints from these facts, were they not already, in general, too wise or too proud to learn from their *inferiors*, the fowls of the air and the beasts of the field."

As has been the case both with the golden and the white-tailed eagle of the eastern continent, this American species has, in consequence of the difference in colour between the young and the mature birds, and the length of time which the former colour lasts, been regarded and described as two species, the ossifrage when young, and the white-headed eagle when old. The confusion has been still farther increased by the same name having been given to the young of the sea-eagle of Europe; and thus, while two species have been multiplied into four, the two proper ones have been confounded with each other. Indeed, we are still in want of information respecting the birds of prey in that part of North America, especially, which lies between the valley of the Mississippi and the Rocky Mountains.

THE OSPREY (*Aquila haliaeta*). This is the proper fishing-eagle of the European shores, and also the fishing-hawk of America, which is so well described by Wilson. It has also been described as a buzzard, and named the bald buzzard, from the white upon the head. It is smaller than the eagles which we have described in the former part of this article, and it is also much more aquatic in its habits, but still its

general characters are those of an eagle, and its size and strength, though the latter is by no means so efficient on land as many of the hawks and falcons, entitle it to the same epithet.

The length of the osprey is about two feet, and the extent of its wings not less than five feet and a half, so that it is better winged in proportion than even the most powerful of the falcons, and may rank among the most aerial of all the birds of prey. The beak of this bird is powerfully formed, very much bent at the tip, furnished with a rudiment of a tooth, and of that dark colour which is always an indication of strength in this order of birds. The tarsi are, like those of the true eagles, very short and strong, but, instead of being feathered as in these, they are covered with reticulated scales, and thus bear some resemblance to those of the wading birds. The claws are very large, more especially that on the outer toe, which is reversible. They are, however, without any ridges or grooves on their under sides, and thus they are clutching claws, and not tearing ones.

The cere, the tarsi, and the toes of the osprey, are greyish blue, the under parts of the toes being abundantly furnished with pads or tubercles. The irides are yellow. The prevailing colour on the upper part is blackish brown, with the exception of the hind part of the head, and part of the neck, which is whitish. A streak of deep brown passes down each side of the neck; and the chin and fore part of the neck are streaked with the same colour, passing into lighter on the breast. The rest of the under-part is dull white, passing into pale grey on the vent and tail. The coverts are pale brown, and the quills darker; sometimes relieved with a paler tint on the margins of the feathers, but never possessing any of the rich and warm browns of the land eagles. Three feathers in the middle of the tail are brown, and all the others have white bars on their inner webs. The outer tail-feathers, and first quills of the wings, have their webs very narrow and exceedingly stiff, so that they cannot be ruffled but with the greatest difficulty. The under sides of the wings, and the whole of their marginal parts, as also the plumage on the under parts of the body, are remarkably close and compact, and do not suffer the least injury by being immersed in water. The thighs are feathered down to the articulations of the tarsi; their colour is pure white; but the feathers bear more resemblance to the hair of aquatic animals, than to the feathers of ordinary birds. The young birds have their colours more broken than the old ones; and in very mature age the colours may be stated as being uniform brown on all the upper part except the head, and white on the under part.

In the places which it frequents, this bird is, perhaps, more on the wing than any of the other eagles, but it is always found over the waters; and so far as is known, it commits no depredations on land. It makes its nest in the crevices of rocks, or on the tops of tall trees, and occasionally on the ground among reeds, laying from two to four white eggs, spotted with reddish, rather smaller than those of the domestic hen. Colonel Montagu once saw a nest belonging to a pair of this species, on the top of a ruined chimney on an island in Loch Lomond. It was large and flat, formed of sticks laid across, lined with flags, and resting on the sides of the chimney. From an expression which occurs in some old acts of parliament, there is reason to believe that the bald buzzard was once trained to fishing in England. It is now

rarely met with in this country, residing chiefly near water, especially large rivers and lakes, and feeding principally on fish, which it catches with great eagerness, and on which it pounces with astonishing rapidity, sometimes plunging two feet under the surface of the water, carrying off its captive, and devouring it at leisure at some distance. In the breeding season, it is frequently seen about the Lake of Killarney, in Ireland. It is found in most of the countries of Europe, from Sweden to Greece, and is very common in Siberia, where the inhabitants foolishly believe that a single scratch of its talons is highly poisonous. It has been, moreover, ascertained to inhabit Egypt, Nigritia, Barbary, and Louisiana.—These birds are almost always observed in pairs, except during the prevalence of severe frost, when the waters are congealed, and when they usually separate in quest of milder skies. During the spring and summer months, the bald buzzard frequently is seen hovering over the large rivers in America, or resting on the wing for several minutes at a time, then suddenly darting down and seldom emerging without a fish in its talons. It then shakes off the water, like a mist, and shapes its course to the woods. The following is Wilson's very graphic description of this bird as it appears on the American waters, where, from the deep embayment of the shores, and the vast extent of broad waters, it is a highly interesting bird. "The fish-hawk is migratory, arriving on the coasts of New York and New Jersey, about the twenty-second of September. Heavy equinoctial storms may vary these periods of arrival and departure a few days, but long observation has ascertained that they are kept with remarkable regularity. On the arrival of these birds in the northern parts of the United States, in March, they sometimes find the bays and ponds frozen, and experience a difficulty in procuring fish for many days. Yet there is no instance on record of their attacking birds, or inferior land animals, with intent to feed on them; though their great strength of flight, as well as of feet and claws, would seem to render this no difficult matter. But they no sooner arrive, than they wage war on the bald eagles, as against a horde of robbers and banditti; sometimes succeeding, by force of numbers and perseverance, in driving them from their haunts, but seldom or never attacking them in single combat.

"The first appearance of the fish-hawk in spring, is welcomed by the fishermen, as the happy signal of the approach of those vast shoals of herring, shad, &c. that regularly arrive on our coasts, and enter our rivers in such prodigious multitudes. Two of a trade, it is said, seldom agree; the adage, however, will not hold good in the present case, for such is the respect paid the fish-hawk, not only by this class of men, but generally by the whole neighbourhood where it resides, that a person who should attempt to shoot one of them, would stand a fair chance of being insulted. This prepossession in favour of the fish-hawk is honourable to their feelings. They associate with its first appearance, ideas of plenty, and all the gaiety of business; they see it active and industrious like themselves; inoffensive to the productions of their farms; building with confidence, and without the least disposition to concealment, in the middle of their fields, and along their fences; and returning, year after year, regularly to its former abode.

"The nest of the fish-hawk is usually built on the top of a dead or decaying tree, sometimes not more

than fifteen, often upwards of fifty, feet from the ground. It has been remarked by the people of the sea coasts, that the most thriving tree will die in a few years after being taken possession of by the fish-hawk. This is attributed to the fish-oil, and to the excrements of the bird; but is more probably occasioned by the large heap of wet salt materials of which the nest is usually composed. In my late excursions to the sea shore, I ascended to several of these nests, that had been built in from year to year, and found them constructed as follows:—Externally, large sticks, from half an inch to an inch and a half in diameter, and two or three feet in length, piled to the height of four or five feet, and from two to three feet in breadth; these were intermixed with corn stalks, sea-weed, pieces of wet turf, in large quantities, mullein stalks, and lined with dry sea-grass; the whole forming a mass very observable at half a mile's distance, and large enough to fill a cart, and form no inconsiderable load for a horse. These materials are so well put together, as often to adhere, in large fragments, after being blown down by the wind. About the first of May, the female fish-hawk begins to lay her eggs, which are commonly three in number, sometimes only two, and rarely four. They are somewhat larger than those of the common hen, and nearly of the same shape. The ground colour varies, in different eggs, from a reddish cream, to nearly a white, splashed and daubed all over with dark Spanish brown, as if done by art. During the time, the female is sitting, the male frequently supplies her with fish; though she occasionally takes a short circuit to sea herself, but quickly returns again. The attention of the male, on such occasions, is regulated by the circumstances of the case. A pair of these birds on the south side of Great Egg Harbour river, and near its mouth, were noted for several years. The female, having but one leg, was regularly furnished, while sitting, with fish in such abundance, that she seldom left the nest, and never to seek for food. This kindness was continued both before and after incubation. Some animals who claim the name and rationality of man, might blush at the recital of this fact.

"On the appearance of the young, which is usually about the last of June, the zeal and watchfulness of the parents are extreme. They stand guard, and go off to fish, alternately; one parent being always within a short distance of the nest. On the near approach of any person, the hawk utters a plaintive whistling note, which becomes shriller as she takes to wing, and sails around, sometimes making a rapid descent, as if aiming directly for you; but checking her course, and sweeping past, at a short distance over head, her wings making a loud whizzing in the air. My worthy friend, Mr. Gardiner, informs me, that they have even been known to fix their claws in a negro's head, who was attempting to climb to their nest; and I had lately a proof of their daring spirit in this way, through the kindness of a friend, resident for a few weeks at Great Egg Harbour. I had requested of him the favour to transmit me, if possible, a live fish-hawk, for the purpose of making a drawing of it, which commission he very faithfully executed; and I think I cannot better illustrate this part of the bird's character than by quoting his letter at large.—Beasley's, Great Egg Harbour, 30th June, 1811. Sir—Mr. Beasley and I went to reconnoitre a fish-hawk's nest on Thursday afternoon. When I was at the nest, I was struck with so great violence on the crown of the hat, that I

thought a hole was made in it. I had ascended fearlessly, and never dreamt of being attacked. I came down quickly. There were in the nest three young ones, about the size of pullets, which, though full-feathered, were unable to fly. On Friday morning, I went again to the nest to get a young one, which I thought I could nurse to a considerable growth, sufficient to answer your purpose, if I should fail to procure an old one, which was represented to me as almost impossible, on account of his shyness, and the danger from his dreadful claws. On taking a young one, I intended to lay a couple of snares in the nest, for which purpose I had a strong cord in my pocket. The old birds were on the tree when Captain H. and I approached it. As a defence, profiting by the experience of yesterday, I took a walking-stick with me. When I was about half way up the tree, the bird I send you struck at me repeatedly with violence; he flew round in a small circle, darting at me at every circuit, and I striking at him. Observing that he always described a circle in the air, before he came at me, I kept a hawk's eye upon him, and the moment he passed me, I availed myself of the opportunity to ascend. When immediately under the nest, I hesitated at the formidable opposition I met, as his rage appeared to increase with my presumption in invading his premises. But I mounted to the nest. At that moment he darted directly at me with all his force, whizzing through the air, his choler apparently redoubled. Fortunately for me, I struck him on the extreme joint of the right wing, with my stick, which brought him to the ground. During this contest, the female was flying round and round at a respectful distance. Captain H. held him till I tied his legs together with my handkerchief; the captain felt the effect of his claws. I brought away a young one to keep the old one in a good humour. I put them in a very large coop; the young one ate some fish, when broken and put into its throat; but the old one would not eat for two days. He continued sullen and obstinate, hardly changing his position. He walks about now, and is approached without danger. He takes very little notice of the young one. A Joseph Smith, working in the field where this nest is, had the curiosity to go up to look at the eggs: the bird clawed his face in a shocking manner; his eye had a narrow escape; I am told that it has never been considered dangerous to approach a hawk's nest. If this be so, this bird's character is peculiar; his affection for his young, and his valiant opposition to an invasion of his nest, entitle him to conspicuous notice. He is the prince of fish-hawks: his character and his portrait seem worthy of being handed to the historic muse. A hawk more worthy of the honour which awaits him could not have been found. I hope no accident will happen to him, and that he may fully answer your purpose.—Yours, Thomas Smith. . . . This morning the female was flying to and fro, making a mournful noise.

"The young of the fish-hawk are remarkable for remaining long in the nest before they attempt to fly. Mr. Smith's letter is dated June 30th, at which time, he observes, they were as large as pullets, and full feathered. Seventeen days after I myself ascended to the same hawk's nest, where I found the two remaining young ones seemingly full grown. They made no attempt to fly, though they both placed themselves in a stern posture of defence as I examined them at my leisure. The female had procured a

second helpmate; but he did not seem to inherit the spirit of his predecessor, for, like a true step-father, he left the nest at my approach, and sailed about at a safe distance with his mate, who showed great anxiety and distress during the whole of my visit. It is universally asserted, by the people of the neighbourhood where these birds breed, that the young remain so long, before they fly, that the parents are obliged at last to compel them to shift for themselves, beating them with their wings, and driving them from the nest; but that they continue to assist them even after this, I know to be a fact, from my own observation, as I have seen the young bird meet its parent in the air, and receive from him the fish he carried in his claws. The flight of the fish-hawk, his manœuvres while in search of fish, and his manner of seizing his prey, are deserving of particular notice. On leaving the nest, he usually flies direct till he comes to the sea, then sails around, in easy curving lines, turning sometimes in the air as on a pivot, apparently without the least exertion, rarely moving the wings, his legs extended in a straight line behind, and his remarkable length, and curvature or bend of wing, distinguishing him from all other hawks. The height at which he thus elegantly glides is various, from one hundred to one hundred and fifty and two hundred feet, sometimes much higher, all the while calmly reconnoitering the face of the deep below. Suddenly he is seen to check his course, as if struck by a particular object, which he seems to survey for a few moments with such steadiness, that he appears fixed in air, flapping his wings. This object, however, he abandons, or rather, the fish he had in his eye has disappeared, and he is again seen sailing around as before. Now, his attention is again arrested, and he descends with great rapidity, but, ere he reaches the surface, shoots off on another course, as if ashamed that another victim had escaped him. He now sails at a short height above the surface, and, by a zig-zag descent, and without seeming to dip his feet in the water, seizes a fish, which, after carrying a short distance, he probably drops, or yields up to the bald eagle, and again ascends, by easy spiral circles, to the higher regions of the air, where he glides about in all the ease and majesty of his species. At once, from this sublime and aerial height, he descends like a perpendicular torrent, plunging into the sea with a loud rushing sound, and with the certainty of a rifle. In a few moments he emerges, bearing in his claws his struggling prey, which he always carries head foremost, and, having risen a few feet above the surface, shakes himself as a water-spaniel would do, and directs his heavy and laborious course directly for the land. If the wind blow hard, and his nest lie in the quarter from whence it comes, it is amusing to observe with what judgment and exertion he beats to windward, not in a direct line, that is, in the wind's eye, but making several successive tacks to gain his purpose. This will appear the more striking, when we consider the size of the fish which he sometimes bears along. A shad was taken from a fish-hawk near Great Egg Harbour, on which he had begun to regale himself, and had already ate a considerable portion of it; the remainder weighed six pounds. Another fish-hawk was passing Mr. Beasley's, at the same place, with a large flounder in his grasp, which struggled and shook him so, that he dropped it on the shore. The flounder was picked up, and served the whole family for dinner. It is a singular fact, that the hawk

never descends to pick up a fish which he happens to drop either on the land or on the water. There is a kind of abstemious dignity in this habit of the hawk superior to the gluttonous voracity displayed by most other birds of prey, particularly by the bald eagle, whose piratical robberies committed on the present species have been already fully detailed in treating of his history. The hawk, however, in his fishing pursuits, sometimes mistakes his mark, or overrates his strength, by striking fish too large and powerful for him to manage, by whom he is suddenly dragged under; and though he sometimes succeeds in extricating himself, after being taken three or four times down, yet oftener both parties perish. The bodies of sturgeon, and of several other large fish, with a fish-hawk fast grappled in them, have at various times been found dead on the shore, cast up by the waves.

"The fish-hawk is doubtless the most numerous of all its genus within the United States. It penetrates far into the interior of the country up our large rivers and their head waters. It may be said to line the sea coast from Georgia to Canada. In some parts I have counted, at one view, more than twenty of their nests within half a mile. Mr. Gardiner informs me that, on the small island on which he resides, there are at least 'three hundred nests of fish-hawks that have young, which, on an average, consume probably not less than six hundred fish daily.' Before they depart in the autumn, they regularly repair their nests, carrying up sticks, sods, &c., fortifying them against the violence of the winter storms, which, from this circumstance, they would seem to foresee and expect. But notwithstanding all their precautions, they frequently, on their return in spring, find them lying in ruins around the roots of the tree which itself has shared the same fate. When a number of hawks, to the amount of twenty or upwards, collect together on one tree, making a loud squeeling noise, there is generally a nest built soon after on the same tree. Probably this congressional assembly were settling the right of the new pair to the premises; or it might be a kind of wedding, or joyous festive meeting on the occasion. They are naturally of a mild and peaceable disposition, living together in great peace and harmony; for though with them, as in the best regulated communities, instances of attack and robbery occur among themselves, yet these instances are extremely rare. Mr. Gardiner observes, that they are sometimes seen high in the air, sailing and cutting strange gambols, with loud vociferations, darting down several hundred feet perpendicular, frequently with part of a fish in one claw, which they seem proud of, and to claim *high hook* as the fishermen call him who takes the greatest number. On these occasions, they serve as a barometer to foretell the changes of the atmosphere; for when the fish-hawks are seen thus sailing high in the air, in circles, it is universally believed to prognosticate a change of weather, often a thunder-storm, in a few hours. On the faith of the certainty of these signs, the experienced coaster wisely prepares for the expected storm, and he is rarely mistaken.

"There is one singular trait in the character of this bird, which is mentioned in treating of the purple grackle, and which I have had many opportunities of witnessing. The grakles, or crow blackbirds, are permitted by the fish-hawk to build their nests among the interstices of the sticks of which his own is constructed, several pairs of grakles taking up their abode there, like humble vassals around the castle of

their chief, laying, hatching their young, and living together in mutual harmony. I have found no less than four of these nests clustered around the sides of the former, and a fifth fixed on the nearest branch of the adjoining tree; as if the proprietor of this last, unable to find an unoccupied corner on the premises, had been anxious to share, as much as possible, the company and protection of this generous bird.

"The fish-hawk is twenty-two inches in length, and five feet three inches in extent; the bill is deep black, the upper as well as the lower cere (for the base of the lower mandible has a loose moveable skin) and also the sides of the mouth, from the nostrils backwards, are light blue; crown and hind part of the head pure white, front streaked with brown; through the eye, a bar of dark blackish brown passes to the neck behind, which, as well as the whole upper parts, is deep brown, the edges of the feathers lighter; shafts of the wing quills brownish white; tail slightly rounded, of rather a paler brown than the body, crossed with eight bars of very dark brown; the wings, when shut, extend about an inch beyond the tail, and are nearly black towards the tips; the inner vanes of both quill and tail feathers are whitish barred with brown; whole lower parts pure white, except the thighs, which are covered with short plumage, and streaked down the fore part with pale brown; the legs and feet are a very pale light blue, prodigiously strong, and disproportionately large, and are covered with flat scales of remarkable strength and thickness, resembling, when dry, the teeth of a large rasp, particularly on the soles, intended, no doubt, to enable the bird to seize with more security his slippery prey; the thighs are long, the legs short, feathered a little below the knee, and, as well as the feet and claws, large; the latter hooked into semicircles, black, and very sharp pointed; the iris of the eye a fiery yellow orange.

"The female is fully two inches longer; the upper part of the head of a less pure white, and the brown streaks on the front spreading more over the crown. The throat and upper part of the breast are dashed with large blotches of pale brown, and the brown bar across the eye is less deep in the tint. The toes of both are exceedingly strong, and much tuberculated; and the claw on the hind toe is an inch and a quarter in measure. The feathers on the hind part of the head are long and narrow, and erected when the bird is excited, as is the case in the land eagles. The eye is without the projecting bony socket, which is common to most of the birds of prey; and the nostrils are very large, triangular, and curved. The two glands on the rump, which supply the bird with oil for lubricating the feathers, are very large, and the contents is a fatty matter, bearing some resemblance in consistency to hog's lard." Thus far we have quoted Wilson's description of this very interesting bird,—a bird which is, perhaps, more characteristic of the American waters than any other which is found on the shores and recesses of that country, which is peculiarly the land of lakes and streams; and where, in consequence, the inhabitants of the waters are of peculiar interest.

Though there are some slight differences between the descriptions of Wilson and the other American describers, and those of the European naturalists that have described this bird as the osprey of our shores, there seems little doubt of the perfect identity of the species in both continents. In Europe, indeed, the bird is said to build less habitually in trees than it

does in America; but that does not form any foundation for a specific difference, as many of the ducks and other aquatic birds which build upon trees in America, build in reeds and bushes in Europe.

THE GREAT AMERICAN EAGLE (*Falco Washingtonii* of Audobon). We mention this species upon the authority of the naturalist whose name we have mentioned, though, at the same time, we have some doubts whether the one which he describes may not be the sea-eagle in its young plumage, or perhaps the harpy eagle, which belongs more to the central latitudes of America, and is one of the short-winged fishing-eagles. The description given by Audobon certainly is that of a very different bird; and, in order that we may do justice both to him and to his subject, we shall quote the entire passage. "It was," says Audobon, "in the month of February, 1814, that I obtained the first sight of this noble bird, and never shall I forget the delight which it gave me. Not even Herschel, when he discovered the planet which bears his name, could have experienced more rapturous feelings. We were on a trading voyage, ascending the Upper Mississippi. The keen wintry blasts whistled around us, and the cold from which I suffered had, in a great degree, extinguished the deep interest which, at other seasons, this magnificent river has been wont to awake in me. I lay stretched beside our patroon. The safety of our cargo was forgotten, and the only thing that called my attention was the multitude of ducks, of different species, accompanied by vast flocks of swans, which from time to time passed us. My patroon, a Canadian, had been engaged many years in the fur trade. He was a man of much intelligence; and, perceiving that these birds had engaged my curiosity, seemed anxious to find some new object to divert me. An eagle flew over us. 'How fortunate!' he exclaimed; 'this is what I could have wished. Look, sir! the great eagle, and the only one I have seen since I left the lakes.' I was instantly on my feet, and, having observed it attentively, concluded, as I lost it in the distance, that it was a species quite new to me. My patroon assured me that such birds were indeed rare; that they sometimes followed the hunters, to feed on the entrails of animals which they had killed, when the lakes were frozen over, but that, when the lakes were open, they would dive in the day-time after fish, and snatch them up in the manner of the fishing-hawk, and that they roosted generally on the shelves of the rocks, where they built their nests, of which he had discovered several by the quantity of white dung scattered below.

"Convinced that the bird was unknown to naturalists, I felt particularly anxious to learn its habits, and to discover in what particulars it differed from the rest of its genus. My next meeting with this bird was a few years afterwards, whilst engaged in collecting cray-fish on one of those flats which border and divide Green River, in Kentucky, near its junction with the Ohio. The river is there bordered by a range of high cliffs, which, for some distance, follow its windings. I observed on the rocks, which, at that place, are nearly perpendicular, a quantity of white ordure, which I attributed to owls that might have resorted thither. I mentioned the circumstance to my companions, when one of them, who lived within a mile of the place, told me it was from the nest of the brown eagle, meaning the white-headed eagle (*Falco leucocephalus*), in its immature state. I

assured him this could not be, and remarked, that neither the old nor the young birds of that species ever build in such places, but always in trees. Although he could not answer my objection, he stoutly maintained that a brown eagle of some kind, above the usual size, had built there; and added, that he had espied the nest some days before, and had seen one of the old birds dive and catch a fish. This he thought strange, having, till then, always observed that both brown eagles and bald eagles procured this kind of food by robbing the fish-hawks. He said, that if I felt particularly anxious to know what nest it was, I might soon satisfy myself, as the old birds would come and feed their young with fish, for he had seen them do so before.

"In high expectation, I seated myself at about a hundred yards from the foot of the rock. Never did time pass more slowly. I could not help betraying the most impatient curiosity, for my hopes whispered it was a sea eagle's nest. Two long hours had elapsed before the old bird made his appearance, which was announced to us by the loud hissings of the two young ones, which crawled to the extremity of the hole to receive a fine fish. I had a perfect view of this noble bird as he held himself to the edging rock, hanging like the barn, bank, or social swallow, his tail spread, and his wings partly so. I trembled lest a word should escape from my companions. The slightest murmur had been treason from them. They entered into my feelings, and, although little interested, gazed with me. In a few minutes the other parent joined the mate, and, from the difference in size (the female of rapacious birds being much larger), we knew this to be the mother bird. She also had brought a fish: but, more cautious than her mate, she glanced her quick and piercing eye around, and instantly perceived that her abode had been discovered. She dropped her prey, with a loud shriek communicated the alarm to the male, and, hovering with him over our heads, kept up a growling cry, to intimidate us from our suspected design. This watchful solicitude I have ever found peculiar to the female,—must I be understood to speak only of birds?

"The young having concealed themselves, we went and picked up the fish which the mother had let fall. It was a white perch, weighing about five pounds and a half. The upper part of the head was broken in, and the back torn by the talons of the eagle. We had plainly seen her bearing it in the manner of the fish-hawk.

"This day's sport being at an end, as we journeyed homewards, we agreed to return the next morning, with the view of obtaining both the old and young birds; but rainy and tempestuous weather setting in, it became necessary to defer the expedition till the third day following, when, with guns and men all in readiness, we reached the rock. Some posted themselves at the foot, others upon it, but in vain. We passed the entire day, without either seeing or hearing an eagle, the sagacious birds, no doubt, having anticipated an invasion, and removed their young to new quarters.

"I come at last to the day which I had so often and so ardently desired. Two years had gone by since the discovery of the nest, in fruitless excursions; but my wishes were no longer to remain ungratified. In returning from the little village of Henderson, to the house of Dr. Rankin, about a mile distant, I saw an eagle rise from a small enclosure not a hundred

Harpy Eagle.

Sea Eagle

yards before me, where the doctor had, a few days before, slaughtered some hogs, and alight upon a low tree branching over the road. I prepared my double-barrelled piece, which I constantly carry, and went slowly and cautiously towards him. Quite fearlessly he waited my approach, looking upon me with undaunted eye. I fired, and he fell. Before I reached him, he was dead. With what delight did I survey the magnificent bird! Had the finest salmon ever pleased him as he did me? Never. I ran and presented him to my friend, with a pride which they alone can feel who, like me, have devoted themselves from their earliest childhood to such pursuits, and who have derived from them their first pleasures. To others I must seem to prattle out of fashion. The doctor, who was an experienced hunter, examined the bird with much satisfaction, and frankly acknowledged he had never before seen or heard of it.

"The name which I have chosen for this new species of eagle, 'the bird of Washington,' may, by some, be considered as preposterous and unfit; but, as it is indisputably the noblest bird of its genus that has yet been discovered in the United States, I trust I shall be allowed to honour it with the name of one yet nobler, who was the saviour of his country, and whose name will ever be dear to it. To those who may be curious to know my reasons, I can only say that, as the New World gave me birth and liberty, the great man who ensured its independence is next to my heart. He had a nobility of mind, and a generosity of soul, such as are seldom possessed. He was brave, so is the eagle; like it, too, he was the terror of his foes; and his fame, extending from pole to pole, resembles the majestic soarings of the mightiest of the feathered tribe. If America has reason to be proud of her Washington, so has she to be proud of her great eagle.

"In the month of January following, I saw a pair of these eagles flying over the falls of the Ohio, one in pursuit of the other. The next day I saw them again. The female had relaxed her severity, had laid aside her coyness, and to a favourite tree they continually resorted. I pursued them unsuccessfully for several days, when they forsook the place.

"The flight of this bird is very different from that of the white-headed eagle. The former encircles a greater space whilst sailing, keeps nearer to the land and the surface of the water, and when about to dive for fish, falls in a spiral manner, as if with the intention of checking any retreating movement which its prey might attempt, darting upon it only when a few yards distant. The fish hawk often does the same. When rising with a fish, the bird of Washington flies to a considerable distance, forming, in its line of course, a very acute angle with the surface line of the water. My last opportunity of seeing this bird was on the 15th of November, 1821, a few miles above the mouth of the Ohio, when two passed over our boat, moving down the river with a gentle motion. In a letter from a kind relative, Mr. W. Blakewell, dated 'Falls of the Ohio, July 1819,' and containing particulars relative to the swallow-tailed hawk (*Falco furcatus*), that gentleman says—'Yesterday, for the first time, I had an opportunity of viewing one of those magnificent birds which you call the sea eagle, as it passed low over me, whilst fishing. I shall be really glad when I can again have the pleasure of seeing your drawing of it.'

"Whilst in Philadelphia, about twelve months ago, I had the gratification of seeing a specimen of this

eagle at Mr. Brans's museum. It was a male, in fine plumage, and beautifully preserved. I wished to purchase it, with a view to carry it to Europe, but the price put upon it was above my means."

Such is the description given by Audobon of this bird, or rather of the effects the sight of it produced on him; though, as we have before stated, there are some reasons to doubt whether this ought to be considered as a separate species. Indeed, in all those places where eagles range far over countries naturally wide and wild, there are always some difficulties attending their natural history. In North America, the eagle pasture extends from the Northern Lakes to the Gulf of Mexico, or, indeed, it may be said, all the way to South America; and in the course of so extensive a range, and where the seasons are so very variable as they are in this great valley, we may be prepared to meet many differences of appearance, and encounter no small difficulty in ascertaining with perfect correctness whether individual specimens, which are seen occasionally, at long distances from each other, and under different circumstances, be or be not the same species.

It has been alleged by some that the golden eagle, or a species somewhat allied, has been seen on the eastern slopes of the Stony Mountains; and it is not impossible that some such bird may visit this district, which is very analogous to those which the same species of eagle inhabits in Europe; but that which Audobon here describes is positively said to be a fishing eagle; and were it not for the great length of wing which he states it to possess, one would be not a little inclined to regard it as being probably an individual of the following species:—

THE HARPY EAGLE (*Harpia destructor*). This is also a fishing eagle, and belongs to different pastures from the sea eagle, the osprey, and the other long-winged fishers. It is a very large bird; and its beak and claws, which are invariably larger in proportion as these birds have more of the fishing habit, are very formidable in appearance. The general aspect of the bird is, however, somewhat feeble, and not at all in accordance with its size; and there is a restlessness about it which is not characteristic of the more powerful eagles, the habit of which is repose, in all cases where they are not under the excitement of seeking their prey. From the figure given in the plate, EAGLES, and the following description, some judgment may be formed of the appearance, and partially, at least, of the character of this large bird. Its predatory habits are denoted by its very robust legs, and the extraordinary curvature of its beak and talons; the upper mandible suddenly curving downwards with a strong arch or hook towards the point, which is excessively sharp. By this structure, and the shortness of the wings, it is readily distinguished from the other eagles. The usual length of an adult specimen, as that in the Zoological Gardens, is three feet and a half from beak to tail. The head is covered with thick downy plumage of slaty grey, with a crest of black and grey feathers rising from the back part of the head, which the bird raises considerably when excited. The back and wings and fore part of the neck are black; the feathers of the back terminating rather lighter; from the breast backwards is pure white; and the plumage of the legs is white with blackish bars. The tail is ashy, banded with black; the beak and claws are black, and the legs, which are partly feathered, dusky yellow. Such is the description of a specimen which

was kept for some time in the gardens of the Horticultural Society of London, and afterwards transferred to the collection of the Zoological Society. No very satisfactory account of the native habits of an eagle can be procured when the bird is confined, so that instead of showing its style of flight, it has not room to spread its wings. It is probable, too, that some of the accounts given by travellers of the formidable nature of this eagle are very much exaggerated; and that its real habits are destitute of the grandeur of the eagles of the open air over the wilds, of which it certainly has none of the expression. From all that we can infer respecting the character of this eagle, we should be disposed to conclude that it combines, in part, the manners of the woodland hawks and the vultures; but as the districts over which it extends are varied and difficult to be explored, it is not easy to speak with precision respecting it. The curvature of the bill, all the way from the base, is certainly a character analogous to that of the hawks.

In the richer parts of tropical America, Africa, the East Indies, and also New Holland, there are eagles which bear some resemblance to this one in their habits; being found chiefly over or near the streams, and feeding, in part at least, upon fish. We may mention one or two of these, though they rest chiefly upon museum specimens, or at best upon individuals seen casually.

THE CARACARA EAGLE is a very common bird of prey both in Brazil and in Paraguay. It gets its name from the sound of its voice. It is a low-flying eagle, a very miscellaneous feeder, and, contrary to the habits of the more typical eagles, it comes near human dwellings, and, in part at least, picks up its food while on the ground. It cannot fly high, and walks more than birds of prey generally do. The upper part of the head is black; the neck brownish grey; the breast and shoulders of that colour, barred with brown; the other part of the plumage is blackish brown, except the tail, which is a dirty white colour, with dusky bands, and a black termination. The changes in plumage are too frequent to give the reader an accurate description. The caracara is so bold as to frequent house-tops, walking about with as little fear as the vulture; and it is said even to carry off the sportsman's game before his eyes. D'Azzara tells us that he has seen four or five of this species hunt down red buzzards and herons; and they are believed to prey upon the American ostrich, lambs, and young fawns.

THE CHILIAN SEA EAGLE. This species, though named from the western shore of South America, is found also on the east, and might, with equal propriety, be named after Brazil, or indeed almost any other part of the continent. The habit of naming birds after individual localities, from which a specimen happens to be brought, occasions no small confusion in natural history. This bird plies along the coasts of the sea and the margins of the large fresh waters, but it is a bird of much less splendour in its habits than the white-headed eagle of the north, or even the osprey. It is not so much a fisher as it is a scavenger, haunting the shores for the purpose of clearing them of the refuse of animal matter, much in the same way as the vultures do upon land. The plumage of a mature bird is greyish on the upper part, with white margins to the feathers on the back and breast, and white on the under part, with feathers on the tarsi, which are also of a whitish colour, pencilled with lines

of greyish brown. This formation of the feet indicates a bird which has not the habit of plunging into the water for the purpose of seizing its prey. We believe there are several other American species resembling

The Chilean Sea Eagle.

these more or less in their habits, but the distinctions between them are involved in much obscurity; and it does not appear that there is anything peculiarly interesting in their history, or that a more intimate acquaintance with them would contribute much to our real knowledge of the feathered race.

SOUTH AFRICAN EAGLE. This species inhabits the country about the Cape of Good Hope, but it is supposed to extend over a great part of southern Africa; indeed, over all the country to the southward of the Great Desert. It is more of a land eagle than those which have been mentioned as inhabiting South America, is subject to great changes of plumage, being tawny chestnut when young, and brown, marked with black, when old.

THE WHITISH AFRICAN EAGLE. This species, as mentioned by Le Vaillant, and some other travellers, is thus described:—Whitish, variegated above with yellowish brown, the black barred with white; back of the head slightly crested. About a third smaller than the golden eagle, and of a more slender shape; first observed in the regions of Africa that confine on the Cape of Good Hope. This eagle pursues its game with such agility that hardly any bird can outstrip it. It is partial to a sort of wood-pigeon, whose flight is also very rapid, but which rarely escapes its fangs. It likewise subsists on wood-partridges, and on a very diminutive kind of antelope, which occurs only in the forests. There, concealed behind the thick branch of a tree, this eagle watches his prey, which he seizes by rushing down on it without noise. No sooner has he accomplished the capture than all the crows in the neighbourhood flock around him to share in the spoil; but he defies alike their approach and their clamour, so that they are contented to remain under the tree on which he makes his repast, and pick up the fallen fragments. He never eats his game on the ground, but always bears it to some lofty station, and plucks off the feathers before he despatches it. "But what is very extraordinary," observes Le Vaillant, "and seems difficult of belief in a bird whose ordinary food consists of birds,

is, that the smallest of them may fly, or remain near him, with impunity, and even alight on his eyrie, for he not only does them no harm, but becomes their protector, and defends them against other birds of prey." But he suffers no ravenous bird to approach his domain, chasing and harassing it till it fétres. When tranquil, and sated with food, he repeats, for hours together, a weak and shrill cry. The nest is placed on the top of the highest trees, and contains two white eggs, as large as those of the turkey hen, and rounder. The male and female perform alternately the function of incubation.

THE VOCIFEROUS, or SCREAMING EAGLE, is described in the following terms:—Rusty brown, waved with black; head, neck, breast, and tail white. This appears to be the principal fishing eagle of Southern Africa. The claw, which is slightly visible, is covered with long frizzled down. The female is stronger than the male, but less brilliant in her attire. The sexes are inseparable companions, hunting, flying, and resting together. They subsist chiefly on fish, darting down from the air with inexpressible celerity on such as they perceive, striking the surface of the water with a loud noise, and even submerging their whole body to secure their prize. They also devour a sort of large lizard which abounds in some of the African rivers, and occasionally antelopes, but never birds. Their loud and clamorous call resounds through the vast solitudes of Southern Africa. They are rare at the Cape of Good Hope, and seldom met with till about sixty or eighty leagues in the interior of the country; but the district in which they most frequently occur is about the Bay of Lagoa. Like most other eagles, they place their nest either on the top of lofty trees, or on the points of rocks, and line it with wool, feathers, &c. The eggs are shaped like those of the turkey, but larger, and also whiter.

In many parts of India there are eagles, and probably the imperial eagle of Europe may be found in that country, altered by climate, as it appears that birds of prey, contrary to the habit of the more powerful predatory mammalia, have their characters softened in the warmer countries. Many places of India, especially the Ghauts, or rocky passes which border the table land in the southern parts, are well adapted for the habits of eagles. The following figure represents what is sometimes called the Pondicherry eagle,

Pondicherry Eagle.

though it is highly probable that it ranges along the slopes of the mountains on both coasts. It is also said that there are eagles of a very large size in the eastern islands; and, from the character of the coun-

try, this is highly probable, though we are but little acquainted with the fact.

THE WEDGE-TAILED EAGLE is a native of New Holland, and is about the same proportions as the golden eagle of Europe, but of smaller size, and having the tail wedged or pointed. It is represented as preying upon the emu, and the young of the kangaroo.

EARTH NUT is the *Bunium flexuosum* of Linnaeus, and is found in woods and sometimes in pastures. It has a tuberous root, about the size of a hazel nut, of a sweetish agreeable taste, and eagerly sought for by pigs; indeed, none of the plants are to be met with where pigs are allowed to range. The *Arachis hypogæa*, a South American leguminous plant, is also called the earth nut.

EARTHQUAKE. This is the most terrific of all natural phenomena, and yet, like many other phenomena which appear to deface the fair form of nature, it in reality comes with "healing on its wings." There is no question but that these extraordinary convulsions of the earth's surface are in reality produced by volcanic powers, and that, though lava and scoria are not at once discharged into the atmosphere on the site of the earthquake, yet the best recorded accounts always speak of the great volcanic mountains being at the same time in a state of fearful agitation. Indeed, they have generally been found to precede very violent volcanic eruptions, and they serve, like them, to form vents for the escape of chemical agents, which would otherwise tend to burst asunder and entirely destroy our globe. The character of these extraordinary phenomena will, however, be best understood by furnishing a few details from eye-witnesses to their devastating effects.

The older natural historians teem with the most exaggerated accounts of earthquakes, and the miraculous interposition of relics in checking their progress. Passing, however, by these day-dreams of the earlier naturalists, we come to the great earthquake of 1750, which was felt in three-quarters of the globe at once, and which, for a time, deranged the boundaries of the ocean as much as it affected the land. It commenced at Lisbon on the last day of October; and, according to historians, it began with a thick fog, which was soon dissipated by the heat of the sun. No wind was stirring; the sea was calm, and the weather as warm as in June or July in this country. At thirty-five minutes after nine, without the least warning, except a rumbling noise, a most dreadful earthquake shook, by short but quick vibrations, the foundations of all the city, so that many buildings instantly fell. Then, with a scarce perceptible pause, the nature of the motion was changed, and the houses were thrown from side to side, with a motion like that of a wagon violently driven over rough stones. This second shock "laid almost the whole city in ruins, with prodigious slaughter of the people." The earthquake lasted in all about six minutes. At the moment of its beginning, some persons on the river, near a mile from the city, heard a noise as if their vessel had run aground, though they were then in deep water; and at the same time they saw the houses falling on both sides of the river. The bed of the river Tagus was in many places raised to its surface; ships were driven from their anchors, and thrown together with great violence; nor did their commanders know

whether they were afloat or aground. A large new quay sank to an unfathomable depth, with several hundreds of people who were upon it; nor was one of the dead bodies ever found. The bar was at first seen dry from shore to shore; but suddenly the sea came "rolling in like a mountain," and about Belem Castle the water rose fifty feet almost in an instant. About noon there was another shock, when the walls of several houses that yet remained were seen to open from top to bottom more than a quarter of a yard, and afterwards closed again so exactly that scarce any mark of the injury was left.

At Colares, about twenty miles from Lisbon, and two miles from the sea, on the last day of October, the weather was clear, and uncommonly warm for the season. About four o'clock in the afternoon there arose a fog, which came from the sea, and covered the valleys, a circumstance very unusual at that season of the year. Soon after, the wind changing to the east, the fog returned to the sea, collecting itself, and becoming exceedingly thick. As the fog retired, the sea rose "with a prodigious roaring." The first of November opened with a serene sky, the wind continuing at east; but about nine o'clock the sun began to grow dim, and about half an hour after was heard a rumbling noise like that of chariots, which increased to such a degree that it became equal to the explosions of the largest cannon. Immediately a shock of an earthquake was felt, which was quickly succeeded by a second and third, and at the same time several light flames of fire issued from the mountains, resembling the kindling of charcoal. In these three shocks the walls of the buildings moved from east to west. In another situation, whence the sea-coast could be discovered, there issued from one of the hills, called the *Fojo*, a great quantity of smoke, very thick, but not very black. This still increased with the fourth shock, and afterwards continued to issue in a greater or less degree. Just as the subterranean rumblings were heard, the smoke was observed to burst forth at the *Fojo*, and the quantity of smoke was always proportioned to the noise. On visiting the place whence the smoke was seen to arise, no signs of fire could be perceived near it.

At Oporto (near the mouth of the river Douro) the earthquake began about forty minutes past nine. The sky was very serene, when a dreadful hollow noise like thunder, or the rattling of coaches at a distance, was heard, and almost at the same instant the earth began to shake. In the space of a minute or two the river rose and fell five or six feet, and continued to do so for four hours. It ran up at first with so much violence, that it broke a ship's hawser. In some parts the river opened, and seemed to discharge vast quantities of air; and the agitation in the sea was so great, about a league beyond the bar, that air was supposed to have been discharged there also.

St. Ube's, a sea-port town about twenty miles south of Lisbon, was entirely swallowed up by the repeated shocks and the vast surf of the sea. Huge pieces of rock were detached at the same time from the promontory at the west end of the town, which consists of a chain of mountains containing fine jasper of different colours.

The same earthquake was felt all over Spain, except in Catalonia, Aragon, and Valencia. At Ayamonte (near where the Guadiana falls into the Bay of Cadiz), a little before ten o'clock on the first of

November, the earthquake was felt; having been immediately preceded by a hollow rushing noise.—Here the shocks continued for fourteen or fifteen minutes, damaged almost all the buildings, throwing down some, and leaving others irreparably shattered. In little more than half an hour after, the sea and river, with all the canals, overflowed their banks with great violence, laying under water all the coasts of the islands adjacent to the city and its neighbourhood, and flowing into the very streets. The water came on in "vast black mountains," white with foam at the top, and demolished more than one-half of a tower at the bar named *De Canala*.

At Gibraltar, the earthquake was not felt till after ten. It began with a tremulous motion of the earth, which lasted about half a minute. Then followed a violent shock; after that, a trembling of the earth for five or six seconds; then another shock not so violent as the first, which went off gradually as it began.—The whole lasted about two minutes. Some of the guns on the battery were seen to rise, others to sink, the earth having an undulating motion. Most people were seized with giddiness and sickness, and some fell down; others were stupified; and many that were walking or riding felt no motion in the earth, but were sick. The sea rose above six feet, and then fell so low, that boats and all the small craft near the shore were left aground, as were also numbers of small fish. The flux and reflux lasted till next morning, having decreased gradually from two in the afternoon.

In Africa the earthquake was felt almost as severely as it had been in Europe. Great part of the town of Algiers was destroyed. At Arzilla (a town in the kingdom of Fez), about ten in the morning, the sea suddenly rose with such impetuosity, that it lifted up a vessel in the bay, and threw it with such force on the land, that it was broken to pieces. At Fez and Mequinez, great numbers of houses fell down, and a multitude of people were buried in the ruins.

At Morocco, by the falling down of the houses, many people lost their lives; and about eight leagues from the city, the earth opened and swallowed up a village with all the inhabitants, amounting to about ten thousand persons, together with all their cattle, &c. and soon after the earth closed again in the same manner as before. At Salle, a great deal of damage was done. Near a third part of the houses were overthrown; the waters rushed into the city with great rapidity; and left behind them great quantities of fish.

In the city of Funchal, in the island of Madeira, a shock of this earthquake was first perceived at thirty-eight minutes past nine in the morning. It was preceded by a rumbling noise in the air, like that of empty carriages passing hastily over a stone pavement. The inhabitants felt their houses move with a tremulous motion, vibrating very quickly.—The shock continued more than a minute; during which space, the vibrations, though continual, were weakened and increased in force twice very sensibly. The increase after the first remission of the shock was the most intense. The noise in the air accompanied the shock during the whole of its continuance, and lasted some seconds after the motion of the earth had ceased; dying away like a peal of distant thunder rolling through the air. At three quarters past eleven the sea, which was quite calm, it being a fine day, and no wind stirring, retired suddenly some paces; then

rising with a great swell, without the least noise, and as suddenly advancing, overflowed the shore, and entered the city. It rose fifteen feet perpendicular above the high-water mark, although the tide, which flows there seven feet, was then at half ebb. The water immediately receded; and, after having fluctuated four or five times between high and low-water mark, it subsided, and the sea remained calm as before. In the northern part of the island the inundation was more violent, the sea there retiring above one hundred paces at first, and, suddenly returning, overflowed the shore, forcing open doors, breaking down the walls of several magazines and storehouses, leaving great quantities of fish ashore and in the streets of the village of Machico. All this was the effect of one rising of the sea, for it never afterwards flowed high enough to reach the high-water mark. It continued, however, to fluctuate here much longer before it subsided than at Funchal; and in some places to the westward, it was hardly perceptible.

In many parts of Germany the effects of the earthquake were very extraordinary. Throughout the duchy of Holstein, the waters were violently agitated, particularly those of the Elbe and Trave. In Brandenburg, the waters of a large lake called Libsec ebbed and flowed six times in half an hour, with a dreadful noise, the weather being then perfectly calm. The same agitation was observed in the waters of the lakes called Muplgast and Netzo; but at this last place they also emitted an intolerable stench.

In our own island the effects of the earthquake were very perceptible, though not felt with the same terrific violence as on the continent of Europe. At Eyam Bridge, in Derbyshire, some miners who were at the bottom of a shaft about four hundred and fifty feet in depth, were thrown to another part of the gallery where they were working, and the neighbouring waters were violently agitated.

At Loch Lomond, in Scotland, the water was suddenly hurled against its banks, but immediately subsided, till it was as low in appearance as any body then present had ever seen it in the greatest summer-drought. Instantly it returned towards the shore, and in five minutes' time rose again as high as before. The greatest perpendicular height of this swell was two feet four inches. A still more remarkable phenomenon attendant on the earthquake in this lake was, that a large stone lying at some distance from the shore, was forced out of its place in the lake upon dry land, leaving a deep furrow in the ground along the way in which it had moved.

In Loch Ness, about half an hour after nine, a very great agitation was observed in the water. About ten the river Oich, which runs on the north side of Fort Augustus into the head of the loch, was observed to swell very much, and run upwards from the loch with a pretty high wave, about two or three feet higher than the ordinary surface. The motion of the wave was against the wind, and it proceeded rapidly for about 200 yards up the river. It then broke on a shallow, and flowed three or four feet on the banks, after which it returned gently to the loch. It continued ebbing and flowing in this manner for about an hour, without any such remarkable waves as the first; but about eleven o'clock, a wave higher than any of the rest came up, and broke with so much force on the low ground on the north side of the river, that it ran upon the grass upwards of thirty feet from the river's bank.

At Kinsale, between two and three in the afternoon, the weather being very calm, and the tide near full, a large body of water suddenly poured into the harbour with such rapidity, that it broke the cables of two sloops, each moored with two anchors, and of several boats lying near the town. But just at the time that a great deal of mischief was apprehended by all the vessels running foul of each other, an eddy whirled them round several times, and then hurried them back again with the same rapidity as before. This was several times repeated; and while the current rushed up at one side of the harbour, it poured down with equal violence at the other. A vessel that lay all this time in the pool did not seem to be in any ways affected by it; nor was the violence of the currents much perceived in the deeper parts of the harbour, but raged with most violence on the flats. The bottom of the harbour, which is muddy, was much altered; the mud being washed from some places, and deposited in others. The perpendicular rise of the water at one quay was measured, and found to be five feet and a half; and is said to have been much higher at another, where it overflowed, and poured into the market-place with such rapidity, that some people who were on the quay immediately ran off, and yet could not prevent themselves from being overtaken and immersed knee-deep in the water. The agitations extended several miles up the river; but, as in the harbour, were most perceived in the shallowest places. The successive risings and fallings of the water continued about ten minutes, and then the tide returned to its natural course. Between six and seven in the evening, the water rose again, though not with so great violence as before, and it continued to ebb and flow alternately till three in the morning. The waters did not rise gradually at first; but, with "a hollow and horrid noise, rushed in like a deluge, rising six or seven feet in a minute, and as suddenly subsiding. They were as thick as puddle, very black, and stank intolerably." From different accounts it appeared, that the water was affected in a similar manner all along the coast to the westward of Kinsale.

Such were the phenomena of this very remarkable and destructive earthquake, which extended over an immense tract of country. The earthquakes, however, which in the year 1783 ruined a great part of Italy and Sicily, though much more confined in their extent, seem to have been not at all inferior in violence. Sir William Hamilton, who wrote a particular account of their effects, informs us, that "if, on a map of Italy, and with your compass on the scale of Italian miles you were to measure off twenty-two; and then, fixing the central point in the city of Oppido (which seemed to be the spot where the earthquake had exerted its greatest force), form a circle (the radii of which will be twenty-two miles), you will then include all the towns, villages, &c. that have been utterly ruined, and the spots where the greatest mortality happened, and where there have been the most visible alterations on the face of the earth: then extend your compass on the same scale to seventy-two miles, preserving the same centre, and form another circle, you will include the whole country that has any mark of having been affected by the earthquake. A gradation was plainly observed in the damage done to the buildings, as also in the degree of mortality, in proportion as the countries were more or less distant from this supposed centre of the evil." Another cir-

cumstance was particularly remarked, in which this earthquake differed very considerably from others, viz. that if two towns were situated at an equal distance from this centre, one on the hill, the other on the plain or in a bottom, the latter always suffered more by the shocks of the earthquakes than the former.

Sir William Hamilton, who was ambassador from this country to the court of Naples, thus describes the effects of the earthquake in that country:—"I travelled (says he) four days in the plain, in the midst of such misery as cannot be described. The force of the earthquake there was so great, that all the inhabitants of the towns were buried, alive or dead, in the ruins of their houses in an instant. The town of Polistene was large, but ill situated between two rivers that were subject to overflow. Two thousand one hundred, out of 6,000, lost their lives here on the fatal 5th of February." At Castel Nuova, the princess Gerace Grimaldi, with 4,000 of her subjects, perished on the same day by the explosion; for such it appears to have been. Some who had been dug alive out of the ruins, told our author, that they had felt their houses fairly lifted up, without having the least previous notice. An inhabitant of Castel Nuova was at that moment on a hill overlooking the plain; when, feeling the shock, and turning round, instead of the town, he saw only a thick cloud of white dust, like smoke, the natural effect of the crushing of the buildings and the mortar flying off.

The town of Castel Nuova was so effectually destroyed by this dreadful shock, that neither vestige of house or street remained, but all lay in one confused heap of ruins. Castillace and Milicusco, which our author next visited, were both in the same situation. Terra Nuova, situated in the same plain, stood between two rivers, which with the torrents from the mountains, had, in the course of ages, cut deep and wide chasms in the soft sandy clay soil of which it is composed. At Terra Nuova, the ravine or chasm is not less than 500 feet deep, and three quarters of a mile broad. Here the accounts of the earthquake were confused, by not having the situation of the place and nature of the soil explained. It was said, that a town had been thrown a mile from the place on which it stood, without mentioning a word of the ravine; that woods and corn-fields had been removed in the same manner, "when in truth (says our author) it was but upon a large scale what we see every day upon a smaller; when pieces of the sides of hollow ways, having been undermined by rain waters, are detached by their own weight. Here, from the great depth of the ravine, and the violent motion of the earth, two huge portions of the latter, on which a great part of the town stood, which consisted of some hundred houses, had been detached into the ravine, and nearly across it, at about the distance of half a mile from the place where they formerly stood; and what is very extraordinary, many of the inhabitants who had taken this singular leap in their houses, were nevertheless dug out alive, and some unhurt." Our author's guide there, who was both a priest and physician, having been buried in the ruins of his house by the first shock, was thrown out of it and delivered by the second, which immediately followed the first; and there were many well attested instances of the same thing having happened in different parts of Calabria. At Terra Nuova, however, only 400 out of 1600 inhabitants were left alive.

In other parts of the plain, situated near the ravine and near the town of Terra Nuova, our author saw many acres of land, with trees and corn-fields, that had been detached into the ravine, frequently without having been overturned; so that the crops were growing as well as if they had been planted there. Other such pieces were lying in the bottom in an inclined situation; and others again that had been quite overturned. In one place, two of these immense pieces of land having been detached, opposite to one another, had filled the valley, and stopped the course of the river, the waters of which were forming a great lake; "and this (says our author) is the true state of what the accounts mention of mountains that had walked, and having joined together, stopped the course of a river, and formed a lake."

Having thus described two of the most remarkable earthquakes in the olden time, which are valuable from their being well authenticated, we may now briefly notice a most extraordinary natural phenomenon of this description, which occurred in 1812. The state of Missouri, which forms one of the western settlements of the United States of America, was the theatre of this catastrophe; and we cannot do better than furnish a condensed view from the account given by Mr. Flint, in his "Recollections of the Valley of the Mississippi." This traveller, who visited the country about seven years after the event, says, that "from all the accounts corrected by one another, and compared with the very imperfect narratives which were published, I infer that the shock of these earthquakes in the immediate vicinity of the centre of their force, must have equalled, in their terrible heavings of the earth, any thing of the kind that has been recorded. I do not believe that the public have ever yet had any adequate idea of the violence of the concussions. We are accustomed to measure this by the buildings overturned, and the mortality that results. Here the country was thinly settled; the houses, fortunately, were of logs, the most difficult to overturn that could be constructed. Yet, as it was, whole tracts were plunged into the bed of the river. The grave-yard at New Madrid, with all its sleeping tenants, was precipitated into the bed of the stream. Most of the houses were thrown down: large lakes of twenty miles in extent were made in one hour. Other lakes were drained. The whole country to the mouth of the Ohio in one direction, and to the St. Francis in the other, including a front of 300 miles, was convulsed to such a degree as to create lakes and islands, the number of which is not yet known, to cover a tract of many miles in extent, near the Little Prairie, with water three or four feet deep; and when the water disappeared, a stratum of sand of the same thickness was left in its place. The trees split in the midst, lashed one with another, and are still visible over great tracts of country, inclining in every direction and in every angle to the earth, and to the horizon.

"The inhabitants described the undulation of the earth as resembling waves, increasing in elevation as they advanced; and when they had attained a certain fearful height, the earth would burst, and vast volumes of water, and sand, and pit-coal, were discharged as high as the tops of the trees. I have seen a hundred of these chasms, which remained fearfully deep, although in a very tender alluvial soil, and after a lapse of seven years: whole districts were covered with white sand, so as to become uninhabit-

able. The water at first covered the whole country, particularly at the Little Prairie; and it must, indeed, have been a scene of horror, in these deep forests and in the gloom of the darkest night, and by wading in the water to the middle, to avoid these convulsions, which were occurring every few hours, with a noise equally terrible to the beasts and birds as to men. The birds themselves lost all power and disposition to fly, and retreated to the bosoms of men, their fellow-sufferers in this general convulsion.

"One result of these terrific phenomena was very obvious. The people of this village had been noted for their profligacy and impiety. In the midst of these scenes of horror, all—catholics and protestants, praying and profane—became of one religion, and partook of one feeling. Two hundred people, speaking English, French, and Spanish, crowded together, their visages pale, the mothers embracing their children. As soon as the omen that preceded the earthquakes became visible, as soon as the air became a little obscured, as though a sudden mist arose from the east, all in their different languages and forms, but all deeply in earnest, betook themselves to the voice of prayer.

"The people, without exception, were unlettered backwoodsmen, of the class least addicted to reasoning, and yet it is remarkable how ingeniously and conclusively they reasoned from apprehension sharpened by fear. They remarked that the chasms in the earth were in a direction from south-west to north-east, and they were of an extent to swallow up not only men but houses, 'quick down into the pit.' And these chasms occurred frequently within intervals of half a mile. They felled the tallest trees at right angles to the chasms, and stationed themselves upon the felled trees. By this invention all were saved, for the chasms occurred more than once under these felled trees. Meantime their cattle and their harvests, both here and at New Madrid, principally perished. The people no longer dared to dwell in houses; but they passed this winter and the succeeding one in bark booths and camps, like those of the Indians, of so light a texture as not to expose the inhabitants to danger, in case of their being thrown down."

Our space will not admit of any detailed enumeration of the early theories for illustrating the cause of earthquakes, and it is of but little consequence, as they are of the most vague and visionary kind. Until very lately, they were supposed to arise from the united action of sulphur and coal in the bowels of the earth; there is, however, but little doubt that the real cause, both of earthquakes and volcanoes, may be traced to the blending of large volumes of water with those metals which form the alkaline and earthy bases. These instantly burst into flame, and we well know that no weight, however mighty, or material, however strong, can resist their combined action. Those who have seen a massive iron case, many inches in thickness, burst by the force of a few drops of water converted into steam, will fully comprehend the elastic force of thousands of gallons acted upon by the most intense combustion of potassium or sodium.

Both earthquakes and volcanoes tend very materially to purify the atmosphere, and they have generally been found to follow long periods of disease, if not absolute pestilence, and when indeed some such revivifier was absolutely needed. What is still more important, they serve as moral landmarks to show

how completely we are in the hands of that Providence whose visitations find us as surely on the firm set earth as when we brave the depths of the ocean.

**E A R W I G.** The ordinary English name of the *Forficula auricularia* of Linnaeus, an insect so common as to require but little description to render the reader acquainted with it. The body is of an elongated form, and is terminated by scaly forceps formed of two long and curved horny appendages, pointed at the tip, and having several small teeth on the inner margin. The wing-covers are short and square, not covering more than one-third of the abdomen; the wings are of large size, although but seldom seen, being shut up by means of numerous longitudinal and transverse folds, so as to occupy but a very small space. This insect has so much the appearance of some of the *Staphylinidae* (see BRACHELYTRA) that Linnaeus was induced to place it in the order *Coleoptera*, with which it indeed agrees, in having the wing-covers united (when closed) in a straight line; the transformations, however, which it undergoes do not agree with those of the beetles, the insect retaining its powers of locomotion, and, consequently, of feeding during the pupa state; in which respect, as well as in the structure of the mouth, it resembles the grasshoppers and other orthopterous insects. From these, however, it differs so much, that Dr. Leach, M. Leon Dufour, and others, have formed it into a distinct order, whilst Latreille and his followers unite it with the orthoptera, but form it into a distinct section. In this respect, therefore, it will be seen that the despised earwig assumes a considerable degree of interest, which will not be lessened when we learn that the generally received opinion that it creeps into the brain of sleeping persons through the ears (an opinion current in most countries, as we learn from the names of *perce-oreille* given to it by the French, *oren-wurm* by the Germans, and *oren-metel* by the Dutch) is one of those popular errors which are so difficult to root out. That the ear-wig may on some occasion or other introduce itself into the ear of a person sleeping on the grass or in outhouses, is not more unlikely than that any other insect which resides in holes and crevices in such situations should do the same; but the structure of the human ear would completely prevent any insect from entering the head, whilst the situation itself would evidently be as uncomfortable to the insect as it would be to the person annoyed.

The food of the earwig consists of vegetable matters. It does much mischief in gardens, devouring not only fruits, but also the petals of flowers; indeed they are one of the greatest pests to the florist. We have observed that they are especially destructive to the noble flowers of the dahlia, but we are unable to give any more effectual recipe for their destruction than is contained in the following quaint extract from Old Mouffet:—"The English women hate them exceedingly, because of the flowers of close gilliflowers that they eat and spoyl, and they lay snares for them thus: they set in the utmost void places ox-hoofs, hogs'-hoofs, or old cast things that are hollow, upon a staff fastened into the ground, and these are easily stuffed with cloathes or straw; and when by night the savages creep into them to avoid the rain or hide themselves, on the morning these old cast things being suddenly taken away and shook forth, a great multitude of them fall and are killed with treading upon them." The modern Londoners have

supplied the place of these ox-hoofs in their trim-kept gardens with the hollow claws of lobsters, which give their borders a very droll appearance.

As a set-off against the mischievous propensities of these insects may be mentioned, the peculiar and almost unique instance which the females afford of maternal care for their young progeny. In general the care taken and the labours undergone by female insects in the construction of nests, are but the result of instinct, the parent dying long before the birth of her progeny; but in the earwig the reverse of this takes place. Not only do these females take great care of their eggs, covering them over with their bodies, brooding over them like a hen, and collecting them with great care when scattered about, but show great affection to the young when hatched. These young ones differ only from their parents in their small size, want of wings and wing-covers, and the slenderness and straightness of the forceps at the extremity of the body. In the pupa state they are equally active, and have the wings and wing-cases distinct, but enclosed in flat sheaths of a small size applied closely to the back. The attachment existing between the parent and her young is reciprocal; De Geer having discovered a female in the month of June under a stone sitting upon her progeny, which appeared to be just hatched, and which nestled under their parent like chickens under a hen. Having removed this family into a box with earth, he observed that instead of burrowing into the ground as might have been expected, the young ones crowded under the body and between the legs of their parent, who remained quiet and allowed them to continue in this position for hours together. He fed his captives with morsels of ripe apple, upon which they thrived, casting their skin several times like caterpillars. The parent did not live long in confinement, and the young ones had the cannibalism to eat the dead body of their parent. After this the number of the brood diminished, without any remains of the dead bodies being observed; whence it is to be inferred that the survivors had also devoured their dead bodies. This, however, would most probably be occasioned by the want of their proper food, as they never thus prey upon each other in a state of nature. After the final moulting, the wings are expanded to their full size, in which state they are very beautiful objects, not only for their delicate structure, but from the singular direction of the nervures, which are quite unlike those of any other insect.

There are numerous species of earwigs, six or seven of which are inhabitants of this country. Little is, however, known of their habits. See FORICULA.

EBURNA (Lamarck); — BUCCINUM (Linneus). Lamarck has separated this genus from the Linnæan Buccinum, of which it formed a part: he was led to do so in consequence of the peculiar characters of the umbilicus and of the columella, which is prolonged at the lower end, and forms a canal occupying the remaining part of the left side. In almost every other respect it possesses the same characters as the buccinum. One species, the *Eburna Zeylandica*, is remarkable for the spines with which the umbilicus is filled, and they are only to be observed in that species. The animal closely resembles that of the buccinum. The writer has seen specimens of the genus *Eburna*, in which the channel on the right side was quite closed and concealed, in which state it had every character of the buccinum. These shells are found in the Indian

seas principally, a few in the South seas, but no fossil species have yet been discovered.

ECASTAPHYLLUM (Browne). A genus of tropical plants belonging to *Diadelphia Decandria*, and to the natural order *Leguminosæ*. They are evergreen shrubs, and are easy of culture, and easily raised from cuttings.

ECCREMOCARPUS (Ruiz and Pavon). A genus of South American climbers, belonging to the class *Didymania*, and to the natural order *Bignoniaceæ*. Generic character: calyx bell-shaped, limb of five spreading divisions; corolla tubular, swollen above, throat contracted, limb consisting of five-reflexed lobes; stamens included with the rudiment of a fifth; anthers free, fleshy, divided at the base; style bearing a bilamellated stigma; capsule oval, compressed, papery, one-celled, two-valved; seeds imbricated, with membranaceous wings. These are very suitable climbers for covering the columns in a greenhouse or conservatory, as they are free flowerers, and easily managed and propagated.

ECHASSIERS—stilts. The fifth order into which the feathered tribes are divided, in Baron Cuvier's arrangement. For the propriety of the name, and the relations which they bear to the other orders, we may refer the reader to the article BIRD. They have the lower part of their thighs always naked, and the tarsi are, generally speaking, long. These circumstances enable them to wade into the water without wetting their plumage; and as they in general frequent only the shallows, there are few of them that can swim. Some of them have the bill strong, and these feed upon fishes and aquatic reptiles which they seize in the water. Others have the bill feeble, and they feed upon insects and worms. A few of them also feed upon seeds and other vegetable substances, and they are the species which inhabit farthest from the waters. The greater number have the outer and middle toe united by a membrane at the base, but the inner toe is generally free, and the feet not adapted for swimming. Sometimes, however, the toes are emarginated with membrane; and in many the hind toe is entirely wanting, which in most is so short as not to touch the ground when they walk. With the exception of the ostriches, the cassowaries, the emus, and some others, all the order are well-winged birds, and thus capable of transporting themselves through the air when it becomes necessary for them to shift their pastures with the seasons. The short-winged ones are those which are the least aquatic, but they are very swift of foot, and capable of ranging very freely on the surface of the ground in those parched and semi-desert places on which they are most frequently found. Those which are more aquatic in their habits are generally migratory, either within the same country, or from country to country, to a longer or shorter distance, as circumstances may require.

They are divided by Cuvier into five principal families, and some isolated genera which do not very properly come into any of the larger and more regular divisions. The first family, *Brevipennes* (short wings), includes the ostriches and the allied genera, the *struthiones* of many naturalists, together with the apteryx and some others. The second family, *Pesirostres* (compressed bills), include the bustards, plovers, lapwings, oyster catchers, and several other genera. They are not in general fishing birds, though they inhabit the moist grounds or the margins of the waters. The greater number of them are birds of swift foot,

and spend a great deal of their time on the ground, though most of them are also birds of ready wing when they do take the air. The third family, *Cultrirostris* (knife-shaped bills), are, generally speaking, birds of much larger size than those of the second division, if we except the bustards. They are also more aquatic in their habits, and the flesh of most of them is very inferior for food. They include the cranes, the storks, the herons, the boatbills, and various others. The bills of all this species are fitted for seizing prey of considerable dimensions; which is, however, more frequently fish, reptiles, or garbage, than warm blooded animals in the living state. Some of them have the bill of immense size, an instance of which will be found in the article ADJUTANT. The fourth family, *Longirostris* (long bills), have that organ generally much produced, but varying much in texture and in form, according to the kind of their food, and the mode in which they obtain it. Some of them range along the banks of streams, and pick up refuse, but the greater part feed upon insects, worms, and other small animals, in or near the shallow waters, or the sludgy mud. The fifth family, *Macrodactyles* (long toes), includes those species which have the toes proportionally much larger than those of any of the other species. Some of them have the toes without webs, or only with mere rudiments; but others have them partially webbed or margined for their whole length, and can either run along the waters or occasionally swim. The carrying-bird of New Holland, the pratincole, and the flamingo, are the principal ones which stand apart, and do not strictly belong to any of the five families.

**ECHENEIS** (*Remora*, or Sucker-fish). A genus of soft-finned fishes, with the ventral fins immediately under the pectorals. Their most singular character is the sucker with which they are furnished on the upper part of the head, and by means of which they can attach themselves to rocks, to the bodies of other fishes, to the bottoms of ships, to floating wood, or other substances. But though this organ is called a sucker, it is not capable of performing the operation usually called sucking; that is, they do not, by means of it, extract any part of the substance of that to which they fasten themselves, either for the purpose of holding on in currents, or for that of being borne along on that which floats or otherwise moves in the water. Various stories have been told of those fishes arresting the course of vessels in full sail, and doing other things equally marvellous; but we need hardly add that these are wholly destitute of truth. That a ship would not sail the faster for having these fishes on it is true, for in equal numbers they would have nearly the same retarding effect as barnacles or sea-weed, but it would take a great number of them to have any effect.

The sucker consists of a number of transverse cartilaginous laminae, which are directed obliquely forwards at their external extremities, denticulated on their posterior edges, and moveable at pleasure by the fish.

All the genus have the body elongated and covered with small scales. They have a single soft dorsal fin placed immediately over the anal. The head is quite flat on the upper side; the eyes are placed in the sides; the mouth opens horizontally, and is rounded at the muzzle; the lower jaw is the longest, and both are furnished with small teeth placed cardwise, but with a more regular row around

the sides of the jaws; the front edge of the vomer is also covered with small teeth; the gill-flaps contain eight rays; the stomach is a large cul-de-sac; they have eight or nine cæcums; their intestinal canals are short and simple, and they are without any air-bladder.

These fishes, in one or other of their species, are found in almost all seas, and their peculiar form early drew the attention of observers, and gave occasion to those fabulous stories to which we have already alluded. That the singular apparatus with which the heads of these fishes are furnished answers some important purpose in their economy cannot for a moment be doubted, because we never find a specific organ in any animal without a specific use to which that organ is applied. The sucker in these fishes is fit only for one purpose, that of adhering, and therefore there can be no doubt that this is precisely the use which they make of it; and as it is equally fitted for adhering to fixed and to moveable substances, it is equally efficient as an instrument of repose and an instrument of motion. Furnished with this simple but beautifully-formed apparatus, they have a perfect command of themselves in all seas without the muscular effort necessary for maintaining their position in spite of currents, and making their way for long distances without exertion of their fins. Adhering to the rock by means of the sucker, they can, as the flood races by loaded with those small animals on which they feed, remain perfectly at rest in the very turmoil of the waters, and feed in safety where no other fish can maintain its position. It will be readily understood, that, as the sucker holds on by a perfect expulsion of the water from the surface to which it attaches itself, it will retain its position by not only the pressure of the air, but by that of all the depth of water over it, and if this happens to be equal to about thirty-three feet, it will adhere with the force of about thirty pounds upon each inch of the sucker. This is quite sufficient to retain a small and slender-bodied fish against any rush of the water which we can imagine to occur in the sea; nor would it be easy to pull any of those fishes from the rock by main force. In consequence of this powerful means of adhesion, it can select the swiftest and most powerful fishes in the sea for its beasts of burden, and ride safely through the water, without effort on its own part, and also without very much impeding the motion of the fish to which it adheres. It attaches itself to most of the fast-swimming fishes which play near the surface; but we believe the shark, in one or other of its species, is the one which it prefers, and it is often seen attached to this powerful fish when racing along the deep with more velocity than the fleetest horse can display upon land. In these its excursions, it no doubt finds abundance of food in those small animals which float near the surface, especially in the warmer seas; and while it can be thus employed, it is itself perfectly secure from danger, because if it, once gets hold, the fish to which it is attached can do it no harm, however voracious that fish may naturally be.

There are several species of this fish, and though they are very generally distributed, they are much more abundant in the warm seas than in the cold ones, being most plentiful near the equator, and especially in those intertropical regions, where currents of the water are continually setting. Except for the peculiarity of its structure no fish of this genus is of much interest. They are hardly ever used for food,

as the quantity of flesh on them is but small, and the quality inferior, and in addition we may remark that if a fish has any thing very peculiar about it, that arms the superstition of dislike, such a fish is apt to be loathed, without any very reasonable cause.

*E. remora* is the species which has been longest known; it is found abundantly in the Mediterranean, and is most celebrated for stopping ships in their course, and doing other great feats. It is a trifling fish, not above five or six inches in length, and of an ash colour. It is found occasionally in other seas.

*E. nauerates* is a much larger species, often attaining the length of two feet and a half or three feet. Its back and tail are variously marked with greenish tints, and its sides with brown. Its fins are yellowish with brown borders.

*E. lunata* is about the same size, but it has the dorsal fin very long and sometimes obliterated in the middle, and the caudal fin forked. It is black on the back, and grey on the sides. It is a native of the West Indian seas.

ECHEVERIA (Decandolle). A genus of succulent under-shrubs, natives of Mexico. They are decandrous, and belong to the natural order *Crassulaceae*. Some of the species have handsome flowers, and are very hardy greenhouse plants. They succeed in the same kind of dry soil like other succulents; and no plant is easier propagated, for if the upper leaves only are laid on the surface of a pot of earth, they put forth fibres and become perfect plants.

ECHIDNA. A very singular genus of marsupial mammalia, forming, along with *Ornithorhynchus*, a group which Cuvier has placed in the order *Edentata*, or toothless animals; but of which both the structure and the habits are so peculiar that they do not come very well into this, or indeed into any other part of a system founded on the organisation. In the English books the genus under consideration is confounded with *ornithorhynchus*, under the name of *hystrix*, or *hedgehog ornithorhynchus*; but both the structure and the habits forbid this union. The *ornithorhynchus* is a web-footed animal, inhabiting only the waters, and, from the structure of its mandibles, apparently dabbling in the mud, and feeding upon the small animals which that contains, in the same manner as the dabbling ducks, though it is much more a diving animal than any of the duck family, or than any other of the mammalia which find their food in the waters, and have at the same time the four extremities so much produced, and free of their body as to be entitled to the name of legs. The *Echidna*, on the other hand, are not aquatic; and, though they have the mandibles or jaws produced, and formed of a horny substance, without any teeth except small ones on the palate, they do not frequent the waters, neither are their *bills*, as they may without any impropriety be called, at all adapted for dabbling in the mud. Their tongues are extensible to a considerable distance beyond the extremity of the mandibles; and, therefore, the natural conclusion is, that they are insectivorous. Very little is known of their habits, however, for they do not appear to be very numerous, and they burrow so rapidly in the ground, that even when one is discovered, it is not very easily got hold of. The back, and upper part generally, is so thickly beset with spines, and those spines are so sharp, that, though the animal is not larger than the common hedgehog, it cannot be lifted with impunity; and, indeed, the lifting of it requires more force than would be expected from its size, as it

is firmly fixed to the ground in an instant, and but a few moments elapse, before it is so far down that its back is level with the surface. For a long time these animals, the few that were obtained, were procured in their native country, Australia, either from the natives, or by other collectors of curiosities equally ignorant, or, at all events, equally inattentive to any other consideration than that of obtaining the curious animal and getting a price for it; so that nothing was known of the habits, or of that change of structure to which it has since been found that the female is subject in the course of propagation. The researches of more scientific and observant inquirers have, in later times, removed the greater part of the difficulty; and it is now ascertained that the animals of this, as well as those of the aquatic genus, are true mammalia, suckling their young, though the mammary system is more peculiar in them than in any other of the marsupialia, singular as some of these are.

In consequence of there not being any appearance of mammary glands on the female, and no account having arrived as to the fact of those glands being developed only when the state of the animal requires them, and absorbed when no longer necessary, it became impossible for even the most skilful and judicious comparative anatomists to determine, from dissection of the few specimens which they obtained, whether the animals were mammalia or oviparous and as such forming part of a mongrel, or at all events peculiar race, to which nothing analogous was known, in any other part of the world, or in any other department of zoology. The female being wholly without teats, there being only one common *cloaca*, or vent, as in birds, and some parts of the skeleton having an approximation to the bird structure, it was perhaps not unnatural to conclude that the animals were reproduced by eggs. This was farther rendered, if not more probable, at least more tempting to the belief by announcements that the eggs of the *ornithorhynchus* had been found on the banks of some of the Australian rivers. It was natural, when the mode of reproduction in these animals had become a subject of great interest to naturalists all over Europe, and when, in consequence, there was a great and profitable demand for the animals themselves—it was natural that there should be a strong desire on the part of collectors to find the eggs, because the finding of these would have covered the finder with the glory of having been the means of establishing the most anomalous fact in the whole physiology of the animal kingdom. Accordingly an *ornithorhynchus* was seen escaping into the water, from a little bank in an Australian river, and presently the eggs of a lizard were found close by, and thus there was at least the evidence of juxtaposition that these were the veritable eggs of the *ornithorhynchus*. The finder probably could not, and the naturalists to whom the eggs were submitted in Europe at all events did not, institute any inquiry as to what kind of integuments these eggs really had, and what kind the anomalous animals should have, in accordance with the other parts of their singular physiology. Latterly, indeed, some of the British naturalists threw out a hint that the eggs in question were very like the eggs of lizards, or of reptiles of some kind; but it does not appear that they examined them with so much attention as to enable them to decide the truth of the hint. This is rather a matter of importance; because it shows the necessity of attending to the structure of an animal in all its stages, the egg among the rest, if

it happens to pass through that stage, in order that the learned may escape the charge of playing the cuckoo, by laying the egg in the wrong nest.

Before the discovery of the egg, Francis Bauer, perhaps the finest microscopic dissector and painter of the age, at least since the death of his brother Ferdinand, had given it as his opinion that these animals must be mammalia and not birds. He arrived at this conclusion by a careful examination of the ovaries of the female, which he found, both in their own structure and in that of the rudimental ova which they contained, were of the mammalia character, and by no means that of a bird. This was going to the fountain head, and going there most philosophically; but the discovery, though perfectly sound and philosophical, because in strict accordance with the whole system of nature, was too fine for the eyes even of philosophers, and as Bauer himself had been all along more remarkable for promoting science than seeking either honour or reward for the promoting of it, this, which was in truth the *experimentum crucis*, was not decisive of the question; and popularly in Britain, and even among the scientific men of France, the fact of juxtaposition, on which alone the story of the eggs rested, triumphed over the philosophical demonstration of the ovaries; and up to within a comparatively short period, namely, till the year 1833, a dispute was carried on between the zoologists of France and of England, in which the former contended that the oviparous theory was the true one.

On the part of the British zoologists this controversy was conducted with great ability by Mr. Owen, from whose communication to the committee of science of the Zoological Society, made on the 23rd of October, 1832, we shall by and by make an extract. The dispute was not so much as to whether the animals are or are not produced from eggs or germs of some sort or other, but whether the young are suckled by the mother. In all the marsupial animals, in which the characteristic organs of the female are any thing like perfect, the embryo, when it leaves the internal uterus and is transferred to the abdominal pouch, is not a fully developed animal, but a mere rudiment, though a rudiment bearing no resemblance whatever to the egg of any oviparous animal; and this, together with the character of the ovaries as above noticed, would lead to the conclusion that in echidna there is no departure from the general economy of the division of animals to which it in this respect belongs. The real point at issue was whether these animals do or do not suckle their young, and upon this point the observations of Mr. Owen are quite conclusive, and not only so, but the young have since been found in the suckling state, and with the horny mandibles so perfectly undeveloped, that the mouth, though not of exactly the structure for drawing milk from the nipple, was yet well formed for pressing that substance from pores or small openings in the gland containing it. Mr. Owen admits that though the fact of the suckling is established it would not prove the converse, namely, that the young which was suckled had been brought forth alive; but it goes far, and we think sufficiently far, for proving that the animal comes as properly within the ordinary habits of production among marsupial animals as the kangaroo or any other of the class. Mr. Owen mentions the fact of the length of time that many birds are wholly dependent on their parents for their food, and also that the pigeon and some others supply this food in part from a peculiar

secretion of their own bodies; but the secretion in this case is from the stomach, and it is in part mixed with the partially assimilated food of the old bird, whereas a mammary secretion is formed by a peculiar apparatus, an apparatus which is more peculiar, and has a more complicated operation to perform in marsupial animals than in those which deliver their young from the internal uterus in a perfectly matured state. Thus it appears to us that the fact of the agreement of those singular animals with the rest of the marsupiala, in this, the most important function of their lives, has been completely established. The point is one of the most singular which was ever raised in natural history; and had the proof gone the other way, it would have thrown the whole physiology of the vertebrated animals into a state of uncertainty, by which the progress of real science would have been greatly retarded. Those who take an interest in nature, who love to have the beautiful plan and purpose that runs through the whole, and the perfect agreement of structure and function in every part, not only as making system the instrument of discovering truth, but as leading to those reverential feelings for the Author of Nature, which are so conducive to the intellectual and moral elevation and happiness of man, cannot fail in being grateful to Mr. Owen as his coadjutor, both in Britain and Australia. We shall close our general remarks by our promised quotation from Mr. Owen:—"It affords me much pleasure," says Mr. Owen, "to be able to lay before the committee preparations of the mammary glands from the *Echidna hystrix*, which, as the following description will show, afford an additional instance of the close affinity subsisting between it and ornithorhynchus, notwithstanding the great dissimilarity existing between them in external form and in the nature of their integuments. These glands were discovered in a female specimen not quite arrived at maturity, and which, therefore, in all probability had never been impregnated. They are consequently very small, as compared with those which have been observed in ornithorhynchus, but are precisely analogous in number, form, composition, situation, and mode of termination on the outer surface of the integument.

Echidna.

"The terminal ducts, which are fewer in number than in ornithorhynchus, are similarly grouped together, so as to form a small oval *areola*, three lines in the greater and two in the lesser diameter. Each *areola* is situated half an inch from the mesial line, and three and a half inches from the orifice of the vestibule of the *cloaca*. They are much more readily discovered than in ornithorhynchus, in consequence of the hairs in the *Echidna* being scantier and stiffer, so that the

orifice for their transmission are larger than the orifices of their ducts, which is the reverse of what is observed in *ornithorhynchus*: this, however, may not be the case in the fully developed gland. The *areolæ* are also slightly raised above the surrounding integument, but there is no vascular *rete* or erectile tissue discoverable at these parts. The lactiferous ducts, before penetrating the *corium*, pass between the fibres of a dense *panniculus carnosus* which is here, as in *ornithorhynchus*, interposed between the glands and the integument. The number of the ducts is about sixty. The lobules of the gland are proportionally shorter and broader. Their texture under the lens appears the same as *ornithorhynchus*, that is to say, minutely cellular, and in neither instance consisting of simple *cæca* or elongated follicles. From their small size in the *Echidna* they could not be injected.

"The smallest size which these glands have presented in *Ornithorhynchus* is about one-third larger than those in *Echidna*, now exhibited; in this state, the ovary and uterine tubes were small, and apparently in a state of quiescence. When the ovary is fully developed, and the uterine tubes correspondently enlarged, the mammary glands are about two inches in the long, and one in the short diameter. When the ovary is found large, but flaccid, and apparently after having shed its contents, and when the uterine tubes are still large, then the mammary glands exhibit their greatest development, equalling five inches in the long, and three inches in the short diameter, and being nearly half an inch in thickness. In this state, they may be readily injected; when the lactiferous ducts, to the number of about one hundred and fifty, are seen to terminate in a small oval *areola* on the external surface, not on any raised eminence, but on the level integument, from which the bases grow as freely as in the surrounding parts. Nevertheless, from the glands being confined to the female, and exhibiting, by their variation of size, that their function is temporary; and as the period of their greatest enlargement is shown, by the state of the uterine organs, to be subsequent to the development and expulsion of the *fœtus*; they must be regarded as being true mammary glands destined to provide nourishment for the newly-born animal. The peculiar development of the *panniculus carnosus* over the ventral region, both in *Echidna* and *Ornithorhynchus*, will assist in explaining the mode in which the lacteal secretion is conveyed from the parent to the offspring. The gland lying between this muscle and the expanded cartilages of the ribs and the marsupial bones, is subject to compression, and the young animal need only apply its soft and flexible lips to the *areola* in order to receive the secretion."

The characters are, the muzzle or bill very slender, terminated by a small mouth, with the tongue extensible, like those of those of the ant-eaters and pangolins; and the probability is that, like those creatures, they feed chiefly upon ants and other small ground animals, which are exceedingly numerous in Australia. They are without teeth in the jaws, which instead are terminated by the horny mandibles already mentioned; but in the palate they have numerous rows of little spines. Their feet are very short, and each furnished with five claws, very long, strong, and well adapted for digging. The whole upper part of the body is covered with spines, bearing some resemblance to those of the hedgehog; and when they are apprehensive of danger, and unable to escape from it

by burrowing, they can erect their spines, and roll themselves in a ball like the hedgehogs. Those spines are not their entire covering, but are mixed with hairs, and on the lower part of the body there are hairs of a spinous form, which are tubular and tapering to the points. Their shoulders are so formed as that the foot can work something after the fashion of the wings of birds; and the articulations of the shoulders are kept apart anteriorly by a sort of fural bone. In this respect their shoulders have a resemblance both to the lizard tribe, and to the smaller mammalia which burrow in the ground. There are two species, of which the habits so far as known do not differ, the chief difference being in the covering.

**SPINOUS ECHIDNA** (*E. hystrix*). All covered over with strong spines on the upper part, varying from an inch and a half in length, white for the greater part of their length, but the points black. Those on the tail are erected, but those on the upper part of the body are sloping, unless when the animal is excited. Among the bases of the spines, there is a quantity of coarse short hair of a reddish colour. The head and under part of the body are also covered with short coarse hairs. This species is about the same size as the common hedgehog; it has been found only in New Holland.

**BRISTLY ECHIDNA** (*E. setosa*). This species is a little larger than the former, has the claws shorter, but more hooked and pointed. The whole body is covered with produced bristly hair of a maroon colour, which conceals the spines, and this thick covering reaches as far forward as the eyes. The muzzle is black and naked, all the under part is covered with stiff white hairs, bearing some resemblance to hogs' bristles. This species has been found in Van Diemen's Land, and also in the islands which are situated in Bass's Strait, between that island and New Holland.

**ECHIMYS**—spinous rats. A genus of rodent mammalia, bearing a very considerable resemblance to the common rats in their size, their general form, and several other particulars, but differing entirely from them in the nature of their covering, their haunts, and their geographical distribution.

All the species of this genus, which are pretty numerous, and of which we shall give a short account, are natives of the central and northern parts of America. They are inhabitants of the woods, nestling in the herbage, at the roots of trees, and not coming about houses, or on the cultivated grounds. Their food is understood to consist chiefly of fallen plants and other vegetable matters.

They resemble the rat, properly so called, in the oblong form of their heads. They have four grinders in each side of both jaws, but they are differently formed; those in the upper have ridges of enamel, arranged in the form of the letter V, while in the under jaw they have one simple lamina, and a plaited one. In the upper jaw all these four teeth are nearly of equal size, but in the under jaw the front one is nearly equal to all the other three. The distinguishing characters of the skull are, that the suborbital bone is very much enlarged, that there is no temporal fossa, and that the ridge of the frontal bone is very much produced on each side, so as to afford an ample enfoncement to the eye. The body is elongated like that of the true rats. The tail varies in length in the different species, but it is always round in its section, and often covered with scales, and in one species only it is covered with very fine hair. On the forefoot in

all there are four toes, with a rudiment of a thumb; but there are five toes on the hind feet, and all the toes are armed with very strong crooked claws. Besides the fallen fruits which they find under the trees, they are understood to feed, in the dry season especially, upon bulbous and tuberous roots, of which there is an immense number in the countries which they inhabit. South America is the grand country for tuberous roots, especially those of the *Amaryllideæ*, of which so many have been introduced with such beneficial effect into the gardens of Europe. The stems of all these plants die down during the dry season, and the plants are in a complete state of inaction, or ripen at the same time that there is no herbaceous vegetables, or even shrub upon the dry plains, upon which a vegetable feeding animal can subsist. But during this period of the absence of all vegetable food from the surface, the bulbs treasure up a store of the most nourishing and wholesome food, even for human beings; and the consequence is, that when the breadth of the country appears to be in a state of utter desolation and want, the small rodent animals, which exist in the country in numbers, have a most abundant supply. If the time shall ever come, when we shall be able to see the proper coincidence between the vegetation and the animal life of this part of the world, it will be found to be one of the most interesting volumes in the book of nature; and even now, imperfect and disjointed as our information must be admitted to be, there is no part of the world in which the student of nature is more highly gratified and rewarded than in South America.

And when we duly consider this highly interesting part of the world in all the departments of its natural history, and in all their bearings and relations to each other, we cannot fail to be deeply impressed with the idea of a systematic and harmonious plan running through the whole works of nature, and proclaiming in language not to be neglected or mistaken, that things have all been formed for working in concert with each other, in furtherance of one grand plan and purpose. We have here the most stupendous mountains and the most ample valleys, watered by rivers which have no rivals upon the face of the earth. We have the most powerful volcanic action, and upon the more lofty summits of the mountains, we have, perhaps, the most terrible action of the atmosphere to be found over the whole surface of our globe. Thus, those mountains on that side of the country where they are given up to the intensity of volcanic action and the utmost fury of the storms, are rich beyond all knowledge in other parts of the world, in the most valuable metallic stores; while, in the regions which are more tranquil in their heights, the accumulation of the most precious gems is without a parallel in any other land. Then, the timber of the trees, the medicinal gums, balsams, barks, and other substances, the dyeing woods, the insect dyes, the fruits, the esculent roots, and, in short, all that can grow out of the earth, where shall we find a parallel to what is met with, furnished by all prolific nature, without labour and without price, in South America? Nor can we overlook the navigable rivers, which may be ascended in barks of large burden, to the distance of not less than two thousand miles, while the navigable branches tempt commercial enterprise to nearly the same measure in the cross direction. All this is so temptingly wonderful, whether we seek

for information or for profit, that no thinking mind can pass it over with indifference. Nor are the animals less wonderful. It is true that we have not in a state of nature the grazing animals of any other part of the world—the bison, of which a remnant still lingers in a few spots of Europe, the antelopes of Southern Asia or of Africa, or even any animal that can be compared to the large kangaroo of Australia, to say nothing of the vast herds of roving animals that were once found upon the central savannahs of North America. But what of all this? We find originally in the luxurious forests which have no rivals in grandeur or in the life which they support, the sloths playing the part of grazing animals against the sky, a sort of vegetable feeders that spend all their time with their backs to the ground, as if the very air in South America were able to yield that nourishment to animal life which requires the whole strength of the solid earth in our less propitious portion of the globe. Nor must we forget that while in every other part of the world those animals which are most valuable to man in a state of domestication, the horse and the ox for instance, have, as in wild nature, always faded away in proportion as the human race has multiplied, the case of these very animals in South America has been quite the reverse. The extent to which both wild cattle and wild horses have multiplied, in the more southerly and champaign parts of the country, and that too while the population has been rapidly on the increase, is really something new and eminently striking in the study of our earth. It is impossible to turn one's attention, even in the most casual and cursory manner, to this part of the world without being impressed with the conviction that there is in it every thing that can stimulate the very highest powers of man, and reward his most powerful exertions. But it is a field only for the great of mankind, for those who can understand and appreciate its greatness; and it is doubtful whether it has yet been owned by a people who are worthy of it. Enticing as it is, however, we must withdraw our attention from the general consideration of it, in order to notice the species of that genus of its indigenous mammalia, by which these few desultory remarks have been suggested.

*E. cristata*—the crested spinous rat. This species is the golden-tailed rat of Buffon. In its size and the form of its tail, it bears no inconsiderable resemblance to the common rat; but it differs much in the colour of its covering and the form of its ears. Its colour is maroon with a purple ground, very deep on the back, the sides, and sides of the head, but higher on the under part. This colour extends along the tail for a short distance from its base; but the principal part of that organ is of a rich orange, and there is a spot of the same colour on the face. There is a portion of the tail between the maroon and the orange of a black colour, and the hair upon the whole of the tail is short and fine. The head is large in proportion to the size of the animal; the muzzle and facial line are straight; the eyes are very small; and though the ears have large openings, they do not rise much, if at all, above the level of the head. At the corners of the upper jaw, there are tufts of brown hair forming a sort of whiskers, which are longer than the breadth of the head. The hair on the back of the animal is coarse and strong, flattened in the section, and more than an inch in length, and bears some resemblance to shining pins. It continues on the sides and flanks, but is wanting on the lower part of the body, which is covered with

softer and smoother hair. On this part of the body it is very short, not exceeding one twenty-fourth part of an inch in length, and the individual hairs are round in their section, instead of being flattened like the longer hairs on the upper part. The female has eight mammae, which indicate a progeny rather numerous, though comparatively nothing is known of the manners of the species. It is understood, however, that they are subject to considerable variety of colour, either in different individuals or at different ages; for some have been brought to Europe in which the produced and flattened hairs on the upper part were brown and not maroon; but as these were smaller in size than the more richly coloured ones, it is probable that they were in an immature state. This species lives in the woods under trees, and is supposed to subsist chiefly upon fruits.

*Echimys dactylinus*. This is one of the largest species of the genus, being more than ten inches from the muzzle to the insertion of the tail, and the tail itself is very long, not less than fourteen and a half. The hair upon the body is hard and dry, but not spinous; that on the front is flattened; but on the hinder part it is longer and rougher; and on the upper part of the neck it stands up like a sort of crest. The middle toes of the feet are much larger than the outer ones; the nails on the toes of the fore feet are flat, something in the form of those of the sapajous; but on the hind feet, which have five toes, they are very strong and crooked; the tail, throughout the whole of its length, is naked of hair, and scaly. The manners of this species are very little known.

*Echimys spinosus*. This is the spiny rat of D'Azzara. It is much stouter in the make than the common rat. It stands three inches three quarters high at the shoulder, and four inches at the crupper. The length, from the muzzle to the tail, is ten inches, but the tail is not more than three, if as much. The tail is wholly covered with smooth hair, which completely hides the scales with which the skin among the roots is covered. The eyes are larger than in most of the other species, being not less than a quarter of an inch in diameter. They stand out very prominently, and are about equally distant between the point of the muzzle and the ears. The nose is truncated vertically; the mustachios project only about a quarter of an inch, and the ears do not rise more than a third of an inch from the back of the head. The length of the frontal base is about three quarters of an inch; the ears are naked, and very flexible; the exterior toe on the hind feet is the largest of the whole, but the claw on it is a sort of nail, and does not extend to the same length as those on the other toes, the claws on the intermediate ones being very strong and crooked, and more than a quarter of an inch in length. The body is covered with two sorts of hair, one soft and fine, and of a white colour, the other consisting of two spines about three quarters of an inch in length. These spines are reddish or brown for about one-third from the point, and whitish for the remainder to the roots. They are very much mixed and matted with the softer hair, and there is a tuft or bunch of them before the opening of each ear. The spines of this animal come off in handfuls as easily as the hair of the agoutis. It is a burrowing animal, and forms its hole in a bank where it may be above the reach of the inundations, which are common in the rainy

season in Upper Paraguay, and those other parts of South America in which it is found.

*Echimys hispidus*. This species is about four inches in height and seven in length, including the tail. It is of a reddish brown colour, which is deepest in tint on the back, upon which also they are largest, strongest, and most abundant. Its tail is without hair, scaly, and annulated. This species has been brought to Europe from South America, but the particular locality is not known, and consequently we are wholly ignorant of its habits.

*Echimys delphaidis* is about ten inches in length five in the body, and the same in the tail. The tail is covered with hair to within about an inch of the tip, and that portion has verticillate scales, resembling those on the tail of the common rat. It has spinous hair on the back, of a bright brown colour, darker on the sides, and yellowish on the belly.

*Echimys Cayanensis*. As its name implies, this species is from Cayenne. The body is six inches long; it is bright reddish brown on the back and sides, and pure white on the under part. The hairs on the back are flattened; they are grey at the roots, brown for some part of their length, and reddish at the points. In this species the tarsi of the hind feet are much longer than in any of the former species, which indicates that it is more of a leaping animal.

*Echimys setosus* resembles the former in its structure, and is of about the same size, but it is redder in the colour, and the hair on the upper part more resembles bristles. It is from South America.

**ECHINACEA** (Moench). A genus separated from *Coreopsis* and *Rudbeckia*, belonging to the natural order *Compositæ*. This genus has large high coloured flowers, and is well worth a place in flower borders; they are increased by seed or division of the roots.

**ECHINOCACTUS** (Link and Otto). A large genus of succulent under-shrubs, chiefly South American. Linnæan class and order *Cosandria Monogynia*, and natural order *Cactææ*. This section of the cactææ are all treated like the others; that is, potted in coarse light soil, mixed with lime rubbish, in well drained pots; allowing but little water, and a dry warm part of the house in winter; but in the summer many of them are the better for being exposed to the summer sun and air.

**ECHINODERMATA**. The first class into which Cuvier divides his grand division of *Zoophytes*, or radiated animals; and a very singular and far from an uninteresting division of animated nature they form. They are destitute of anything which can be called a regular skeleton, and they are without those specific organs which characterise not only the vertebrated animals, but most of the divisions of the invertebrata; but still not even what we are accustomed to call the most perfect of the first of these, or the most wonderful in the minuteness of their bodies, and the beautiful perfection of their parts in the second, are superior, in the wonderful power of nature's mechanism, to the zoophytes generally, and to the echinodermata in a particular manner. The term echinodermata means that the skin, or investing integument of the animals, is covered with processes more or less elongated, and more or less ridged or truly spinous, according to the different natures of the animals.

The echinodermata are exceedingly complicated in

their structure; they are invested with a well-organised skin, often armed with points, or with spines which are articulated and moveable, and they have an internal cavity which contains distinct viscera. They have also a sort of vascular system, which extends to all parts of the body, and maintains a communication between these and the intestinal canal, and also the organs of respiration, which are often exceedingly distinct. There are also filaments ramified through the system, which appear to answer the purposes of nerves, though these are not always so regular as the corresponding parts of the system in some other divisions of the invertebrated animals. Cuvier divides them into two orders: those which have feet, or at all events organs which answer nearly the same purpose, and those which have no feet.

The echinodermata with feet are, of course, distinguished from the others by their organs of motion. Their skin or covering is pierced with a great number of small holes arranged in regular series, through which there pass cylindrical tentacula of a membranous substance, terminated by small discs, which are understood to perform the office of aëration. The portions of the tentacula which are in the interior of the body are vesicular, and a liquor which is contained in their cavities is sent at the pleasure of the animal to the external cylindrical part, by which means that part is erected, and each of the projections answers the purpose of a little foot, by means of which the animals perform their progressive movements.

The echinodermata have numerous organs. They have muscles which are very distinct, and serve to execute movements which are often complicated as well as rapid. They are understood to be of two sexes, though these are often united in the same animal, and they are exceedingly prolific.

The order under consideration consists of a good many genera, of which the principal are asterias, or sea star, which are common on many of the rocks on the British shores; encrinurus; echinus, sea hedge-hogs, or sea eggs, which are often gathered upon our shores, and are covered with a shell beset with spines; and holothuria which have an oblong body covered with a leathery crust, and are open at both ends—these abound in many seas, are plentiful in the Mediterranean, and the Malays collect vast numbers of them in the eastern seas, the Chinese being very partial to them as an ingredient in soups. The whole of this division or order are inhabitants of the sea; and though their distribution is pretty general, they are most plentiful in the warm latitudes, and are never found at any great depth. In the tropical seas, where the water is very transparent, where the perpendicular rays of the sun carry their powerful influence to the bottom, and where, in consequence, the production of life is very great, these animals present a very splendid appearance, from the peculiarity of their forms, and often from the richness of their colours. They are shown as sea cucumbers, and a variety of other names, according to the fancy of those persons whose notice they attract, and who are not acquainted with the names given to them by naturalists.

The second order, or the *Echinodermata* without feet, are by no means so numerous as the first; and they all bear some resemblance in their general form to the genus *Holothuria*. They, however, want the

small vesicular feet with which the species of that genus are furnished, and are covered with a leathery skin without any appendages. The genus *Molpadia* also, like *Holothuria*, have a thick cylindrical body, open at both ends, and they have the mouth surrounded by osseous pieces; *Minyas*, which have the body in form of a spheroid depressed at the poles, which are the two openings, and formed into segments along the sides, something after the manner of a melon; *Pirapules*, which have a cylindrical body enlarged at the head, and a fasciculus of filaments at the opposite extremity; *Tethodermes*, which have the body oval, compressed in front, and with a surface incrustated with little grains which are often very hard; *Siphunculus* have the body cylindrical, and they bury themselves in the sand of the sea—in some countries these are much sought after as articles of food; *Bonellia* have the body oval, capable of being much elongated and forked at its extremity, they live very deep in the sand; and *Thalassema*, which have an oblong oval body but not forked like the former, they also live in the sand. The genera of this last order, which bury themselves in the sand, are generally known by the name of worms.

The whole of the division are singular animals; and it is impossible to imagine anything finer than their internal organisation, or more complicated than the number of their parts. They are all without heads, or feet properly so called, or any organs to which we could impute sensation in our ordinary judgment of animals; but notwithstanding this, they are so numerous that it is impossible not to suppose that the functions which they perform in the grand system of nature's operations, are of no ordinary importance. Those which are not covered with a sort of shell or crust, have very much the appearance of living pieces of jelly, or at all events of very soft fleshy matter. Many of these are of a pleasant taste and highly nutritious quality; but there are others which are not only poisonous when eaten, but which are understood to impart poisonous qualities to those fish which feed upon them. The most interesting ones met with upon our shores are the sea hedge-hogs and the star-fish. The former are most frequently found only as empty crusts, with all the projecting tentacula broken off. They are in general shaped something like an apple, with a small aperture on the top which has been the mouth, and its still smaller one at the opposite extremity. The more minute apertures to which the spines have been attached, are arranged in regular rows, reaching nearly from the one opening to the other, something in the same manner as the meridians do on a globe. They are most abundant on the west coasts, and after the Atlantic has been agitated by storms. The sea-stars or star-fish, are found on most parts of the rocky shores at low water, adhering to the rocks by means of filaments; and they are easily known by their star-like shape.

**ECHINOMYIA** (Dumeril). A genus of dipterous insects belonging to the great family *Muscide*, or true flies, having the nose not prominent, the cheeks not produced into horns, the bristle at the extremity of the antennæ simple; the second joint of these organs is longer than the others, and the third is broader, compressed, and somewhat triangle-shaped. The type of the genus is the *Musca grossa*, Linnaeus, one of the largest British dipterous insects, being about the size and having much the appearance of

one of the humble bees. The head of this insect is yellow, and the base of the wings reddish. It makes a loud buzzing noise when on the wing. It settles on flowers in woods. The larva, according to Reaumur, resides in cow-dung; the body is yellow, shining, and conical, with a small claw and two fleshy horns at the head. In the chrysalis case (formed of the indurated skin of the larva), which is also of a conical form, the extremity of the body exhibits two distinct spiracles.

We are inclined to believe that this account which Latreille, indeed, adopted, is founded in error, the fly in question belonging to a group of the family which, so far as has hitherto been satisfactorily observed, is entirely composed of species parasitic upon other insects, in a similar manner to the ichneumons.

The fly is rather uncommon; we have, however, met with it in the winged state at Coombe Wood.

**ECHINOPHORA** (Linnaeus). A genus of hardy herbaceous perennials, one of them a native of England, and known by the name of sea parsnep. They belong to the natural order *Umbelliferae*.

**ECHINOPS** (Linnaeus). A genus belonging to the natural order *Compositae*, commonly called the globe-thistle. They are raised from seeds, and are suitable for filling up vacant places in the shrubberies of the flower garden.

**ECHITES** (Linnaeus). A genus of tropical climbing plants, some of which live in our greenhouses, but the most ornamental are stove plants. Class and order *Pentandria Monogynia*, natural order *Apocynae*. Generic character: calyx five parted; corolla funnel shaped; stamens included or exserted; anthers connected in a circle round the stigma; five scales round the germen; style simple; stigma thick and with the anthers form a cone. The echites are valued for their flowers; they grow well in loam and moor earth, and are propagated by cuttings.

**ECHIUM** (Linnaeus). An extensive genus of shrubs and herbs, the former chiefly African, the latter European. Class *Pentandria*, order *Monogynia*, natural order *Boraginaceae*. Generic character: calyx five parted; corolla, bell shaped; limb of several unequal segments; stamens of different lengths; nut angular. This genus is of easy culture, and propagated by cuttings, layers, or seeds when they are produced.

**EDENTATA**—Toothless. The sixth order into which the mammalia are arranged by Baron Cuvier. The name is, perhaps, about the best that could be adopted in the present state of zoological science; but still it is a name, the foundation of which is a negative, and therefore it is not one which can convey much information. Further than this, it is not quite accurate, as the greater part of the animals included in it are not entirely destitute of teeth even in the jaws, and of those which are the most destitute in those parts, the greater number are supplied with appendages which answer the purpose of teeth, and not a few with teeth on the palate.

Still the animals which are comprehended in this order are of difficult arrangement in any other way; and they have so few characters in common to all the families and genera, that perhaps the best course to be adopted was that in which the name of the order is not tied down to any particular character of any one of its divisions; but rather made the explanation, or expression, of the circumstance in which they all, taken generally, differ the most from the other animals

which have the feet divided into distinct toes, and in which all the animals of this division, how much soever they may differ from each other, yet perfectly agree. Some, indeed, have a greater and some a smaller number of toes; but in all of them the toes, whatever may be their number, are distinct; and they are, in general, armed with claws, which are powerful in proportion to the size of the animals.

Cuvier describes them as being, in his system of arrangement, the last order of the animals—that is the mammalia with toes, and having no teeth in the anterior part of the mouth. He also admits that the only character, of a positive kind, which will apply to them all, is that of having very large claws, not articulated to the toes in the same manner as in the predatory animals, but a sort of shoes with which the toes are specially and separately furnished, and by which their extremities are protected.

Viewing them with reference to their structure and habits, the animals of this order may be said to form a supplemental class of mammalia, less adapted to the present condition of the earth than to some different one which we may suppose to have existed formerly. Among the monumental animals which are found in the earth, there are some which combine in the same specimen organs which, in the living races, belong only to animals of different classes. We find, for instance, that there have been creatures with wings of more than "eagle-spread," and with claws appended to those wings, more formidable than those of the most powerful carnivorous animals of the present time, while the armature of the jaws appears to have been sufficient for all predatory purposes on the part of the owners. We are therefore led to suppose that these hooked claws to the wings may have been organs of suspension, by means of which the animals fixed themselves for rest upon the tall plants by which their remains are accompanied, and which appear to have grown where the surface of the earth was covered with water. None of the existing edentata are furnished with any organs of flight; and their motions upon the earth are, in general, but slow; still many of them have, in the structure of the skeleton, traces of the bird character. Some of them have the same articulation of the shoulder, others an approximation to the same structure of the pelvis, and there are others still which have only a single passage for all excretory purposes.

None of them can strictly be said to be the inhabitants of the surface of the earth; they are either climbers or burrowers; or in the case of at least one species, they are aquatic. The greater number feed upon insects and other small earth animals, which require no biting and little or no mastication. They have in general the tongue extensible, so that it is the instrument used in the capture of their food. The few that are vegetable feeders are, in their habits, the very reverse of those ordinary mammalia which feed on the same substances; they browse the foliage of trees, and not the herbage of the ground.

In their whole aspect they are peculiar; and their covering, though varied in the different genera, has yet a common character. Their hair partakes of the nature of whalebone, and many of them are covered with scales or crusts. In their reproductive system they fall into both the grand divisions of placental and marsupial animals; some bring their young to maturity internally, and others advance them only so far in that way. They, in fact, present so many differ-

ances and anomalies in a comparatively limited number of genera and families, that they perhaps throw more difficulties in the way of a clear understanding of the system of nature, than any other of the vertebrated animals.

They are divided by Cuvier into three tribes; *Tardigrada*, or, "slow walkers;" *Edentata*, or toothless animals, properly so called; and *Monotremata*, or those which have but one cloaca, or vent, as in birds.

The first family consists of but one single living group, the sloths, of which some account will be found in the article *Art*; they have only the fore teeth wanting; for they are provided with cylindrical molars and with pointed canine teeth of greater length; they are furnished with numerous claws to the toes, by means of which they suspend themselves to the branches of trees, and walk or repose with the back downwards.

Connected with this single existing genus, though differing from it by being much larger in size, and also in some other important particulars, there are two extinct genera, both natives of the same parts of the world in which the existing genus is found, that is in South America. These are the *Megatherium*, which from the skeleton must have been an animal of large size, and the *Megalonyx*, which, though larger than any of the existing species, must have been less than the former.

These are, both fossil animals, and, of course, only their skeletons are known to us; but these have been found in a state of sufficient perfection for enabling, at least, some judgment to be formed of what the animals must have been when alive. They appear to have held a sort of middle station between the sloths and the ant-eaters, agreeing with the former in many parts of the skeleton, but being without the produced and pointed canine teeth. Of the state of the country where such formidable animals of this kind were necessary (and if they had not been necessary as part of the general system they would not have existed) we cannot possibly form any idea, but they carry us back to a state of things very different from the present; and from the description of countries which we find the sloths and the ant-eaters now inhabiting, we can at least form some rude guess at that which was more general when the larger animals of similar structure were required for the proper working of the system. The sloths are found only in those parts of South America where the ground is covered with thick forests, and subject to seasonal inundations; and the ant-eaters are found only in places where there is an exuberance of ligneous vegetation, of the substance of which small insects of various kinds, but all in general known by the name of ants, are the natural destroyers. We are, therefore, to infer that, in the early times, when more powerful animals of similar structure, and therefore, as we may suppose, of similar habits, were necessary, there must have been upon the earth a more general and rapid production of ligneous vegetation, which required a still greater abundance of the wood-destroying insects than we find in the tropical forests at the present time, and the greater abundance of this must have rendered a greater number of those animals which prey upon them necessary for the proper working of the system and the due preservation of all the races.

From the form of our globe, the place which it holds in the system, the motions which it performs,

and the consequent mode of the distribution upon it of that influence of the sun which is the grand stimulus of all kinds of life, every species of production and action upon it, wherever it may have taken place, must have been seasonal—must have had its spring, its maturity, its fall, and its repose.

Without any reference to the Great First Cause by which the universe is regulated, our earth is under the controul of far more powerful energies than any of a merely terrestrial character or origin. It is part of the same system, the laws of which are not one-jot affected by anything that can take place on the surface of the earth. The mere quantity, that is, the weight of matter in it, is the only property of it which comes within the general laws of the system; and however the volume, the combinations, or the other apparent qualities of the matter of the earth, may change, the quantity, as measured by the gravitation, must remain the same, unless altered by the direct interposition of the same Being that called it into existence. The orbital motion of the earth must remain constant, with the exception of those small variations in long periods of time which the influence of the other bodies of the system impose upon it; and the extent and limits of which are matters of certain and not very difficult calculation. Those variations are so small, and the periods over which they extend are so long, that they can have no effect whatever upon any part of the economy of the earth's surface during the life of man, or the whole time of man's history. Therefore, we may leave them out of view, and consider the grand seasonal action of the sun upon the earth as being at all times one and the same, as told in the different hours of the day, and the successive days of the orbital revolution.

We have this as an unquestionably sure foundation in all those speculations and inquiries into nature which are of a more general kind than the simple examination of that which comes before our eyes as mortalists. Those speculations are by far the most valuable portions of the subject, for they lead the mind to immortality, and give it immortal hope, which is of far more importance than anything which is confined to our few years of trouble and vexation in this world.

In consequence of this general law of the system, which is far more immutable upon the earth than the laws of the Medes and Persians were upon the subjects of those departed and all-but-forgotten states, we may be sure that the general action of the seasons, as dependent on the sun, must have been the same in all ages, how differently soever the surface of the earth over the whole, or in any region, may have obeyed or been affected by that action. The existence of these last animals which have led us to these few remarks—and we regret that our limits will not admit of our following them out; and we do this the more that we believe the subject is but seldom brought before the public generally, even to such an extent as to call attention to it—the existence of these animals speaks of a time of forests and floodings; and we know that in all places of the world where these are, there are alternating periods of drought. During the flood we may suppose that the whole of the timber-destroying insects were swept away; but that as the eggs of all are proof against every change of nature, and many of them are actually committed to the waters, there was always a store for the production of fresh myriads as soon as the

alternating drought set in, and the waters subsided. While the water was on the surface, and the insects gone, we may suppose that the large animals of which we have spoken were aloft in the trees, performing the same kind of operation which is now, to a less extent, performed by the sloths, that is, pruning the redundancy of the leaves, so that the trees might ripen their fruits and perfect their seeds. Then, when the rains were over, and the insects had come to maturity in their countless numbers, every tree on which the print of decay was set, and where the leaves had ceased to be succulent, the same animals may have descended to feed upon the spoilers, in order to prevent their dead bodies from being carried to waste by the returning waters. At the present time we have only what may be called partial remnants of this extreme of the working of seasons, but still we have enough to give us at least some insight into what must have been the earlier state of things.

The second tribe of this singular order of animals comprises two, or rather three genera; the *Armadillos*, of which an account will be found under the name ARMADILLO; *Oryctopus* (digging foot), a singular burrowing animal of Southern Africa, called the earth-hog by the settlers, and sometimes the *Aardverk*, or "earth-breaker," from the facility with which it burrows in the ground; and *Myrmecophaga*, or the ant-eaters, properly so called, of which some account will be found in the article ANT-EATER. Besides the ant-eaters, properly so called, there is an allied genus, the *Pangolins* (*Manis*), which are covered with imbricated scales, shaped like feathers in some of the species, and in all of them bare at their posterior edges. These last, from the form of their bodies, have been popularly called scaly lizards, but they are not lizards; they are true mammalia, only they are very different from the mammalia of what may be called our era of the world, which feed chiefly upon vegetable matters, or animal ones of larger size than the food of this, requiring to kill or crop their food, or, at all events, to divide or bruise it, and which are furnished with teeth adapted to the kind of food upon which they live.

All the genera of this singular order which we have hitherto enumerated are placental mammalia, bringing forward their young in an internal uterus, until they are completely formed; so that, if the order were arranged, as it might certainly be with some advantage to the system, these would answer to the placental mammalia which inhabit the world more generally, are adapted to all its latitudes, and in their various species to all the kinds of food which it requires, and which are the best known, and therefore to us the typical animals, one or other of which naturally occurs to the mind whenever the word mammalia is mentioned.

The remaining portion of the order, which have so little in common with the portion which has been mentioned, that they might as well be kept separate, are the *Monotrenata*, or those which, like birds, have only one vent. There are but two genera of them, of which some account will be found in the articles ECHIDNA and ORNITHORHYNCHUS. They are marsupial animals, but all their habits are obscure, and nothing is known of the period of advancement at which the young are delivered from the internal uterus, though it has been ascertained that the females have a mammary apparatus for the suckling

of their young. It is worthy of remark, that all the existing edentata are confined to the southern hemisphere, or at least the exceptions are few.

**EDOLIUS** (*Drongo*). A genus of insectivorous birds, which were long, from their colours and other external circumstances, obtained chiefly from stuffed skins, referred not only to different genera, but to different orders, until *Cuvier*, from a careful examination of their structure, assigned them their proper place in the *Règne Animal*. In his arrangement, which, though not, in the nature of things, perfect, as no sagacity can supply the want of facts, is yet by far the best that ever was made, they belong to the dentostrual division of his great order *Passeres*, and to the fly-catcher family of that division. In that arrangement the dentostrual passerines follow immediately after the birds of prey, the shrike family taking the lead, and the fly-catchers following immediately after.

It is impossible not to admire this arrangement. The shrikes are actually, to a considerable extent, birds of prey; that is, they kill and eat birds, though they also eat other animals, as beetles, and the larger flies. The fly-catchers are also birds of prey, killing their own game, instead of living upon garbage, and picking up what they can find. Between them the distinction applies more to the size of the prey than to the habits of the birds; and if an eagle, which catches a hare—a falcon, which strikes down a pigeon—an owl, that mouses—and a small hawk, which catches beetles in its evening flights—are birds of prey, then the same name may, without much impropriety, be given to those birds which catch insects on the wing, which, according to our common notion of things, is a more noble sport than stealing an egg from a nest, or filching a caterpillar out of the curl of a leaf.

The characters of the genus *edolius* are: the bill stout, depressed at the base, a little compressed laterally toward the point, and furnished with a notch or tooth; the upper mandible slightly keeled, arched in the culmen, and hooked at the tip; the lower mandible straight, but inclining upward at the tip; the base of the bill furnished with long and strong bristles, directed forwards; the nostrils, near the base of the bill, lateral, and half closed by a membrane, which is concealed by the bristles; the feet short and feeble, furnished with four toes, the outer and middle one joined as far as the first articulation, and the hind toe stout, but shorter than the middle one; the wings of mean length, the first quill very short, the second shorter than the third, and the fourth or fifth, and sometimes the sixth, the longest in the wing; the tail in most of the species forked, rarely even, and never wedged.

This genus of birds are all natives of the eastern continent, and they are particularly abundant in India and the Oriental Isles, where they are usually seen near the shores of the sea, or the margins of the broad waters. They are great destroyers of insects, especially of bees, in pursuit of which they are active on the wing during the greater part of the day. They are in general gregarious, appearing in flocks in the morning and toward evening, but they spend the night and the heat of the day in the forests, their notes of salutation, when they leave their shady retreat, being often audible at a very considerable distance. Their cry upon these occasions is a sort of loud scream, in which there is not much music; but it is said that their love-songs, which they sing when they are apart, have a good deal of melody in them,

and those of some have been compared to that of the nightingale. As the birds are not together, however, it is impossible to institute a comparison, and there seems to be some tendency to overrate the musical powers of tropical birds. The reason of that may be seen without much difficulty. The sounds uttered by the tree-birds and tree-mammalia in those parts of the world are in general very harsh and disagreeable. The screaming of parrots, the chattering of monkeys, and the howling of the larger apes, to say nothing of the yelling of beasts of prey and the hissing of serpents, or the hollow roarings of crocodiles and alligators, are not the sweetest voices in nature. Hence, when any bird or other creature happens to strike up a noise which is even tolerable, the relief which it gives is music to the ear; and there is no doubt that this is one of the reasons why the songs of the drongos have been reckoned so sweet. They are no doubt at a considerable distance in the scale from those birds which have no love-song, or cry of any kind, save a cherrup or a scream, but they are not quite so far removed as to bring them among the songsters, properly so called.

They build their nests in the tops of the most lofty trees. The eggs, which are usually four in number, are rather large for the size of the birds, of a dull white colour, with black markings. The prevailing colour of the birds is black, with iridescent reflections of purple, green, and other colours; but as the reflected colours of birds do not come out except on near inspection, they appear quite black to ordinary observation. The flavour of their flesh is rank, so that they are of no use in an economical point of view. Their black colour, their screaming, their restless activity, and the offensive nature of their flesh, have procured them the name of "Devil's birds," which they are designated in many places, both by the natives and by Europeans. Vieillot gave the genus the name *Dicrurus*, double tail, or forked tail; but, as many of them have not that character, it is inapplicable. This is one instance of the injudiciousness of founding the name of a genus upon any one external character; for, if the genus is new, the probability is, that the character will not be applicable to it. Nor could there be, even admitting that the practice were a wise one, on the whole, a more absurd perversion of it, than to name a genus from the trivial circumstance of having a forked tail, which is common to so many birds. Other authors have classed the birds variously; some of them have been named, and even described as crows; others as rollers; others as cuckoos; and others again as shrikes; the last of which is near the truth, but even it is not correct, and the birds are really a distinct, and not a badly marked genus, both in their appearance and their habits. The generic name *edolius*, which Cuvier has given them, does not express much certainly, but still it leads to no mistake, and that is a matter of some consequence. It is perhaps not possible to find descriptive names for one-tenth of the genera of birds, or indeed of any other class of animals; and this being the case, the next best thing to be done is to give the genera names which shall be their own, and which shall not convey any erroneous meaning. We shall now mention a few of the species, remarking, at the same time, that, as the birds are exceedingly numerous, especially in the eastern Archipelago, the list cannot be expected to be complete.

*EDOLIUS PUELLUS*.<sup>c</sup> This species was described as

a roller both by Latham and Temminck. It is a native of Java, and most likely of the other islands of the same group. It is about eight inches long: the male has the crown of the head, the neck, the scapulars, the back, and the upper tail-coverts of a very intense and brilliant azure blue; and the rest of the plumage is deep velvet black, with the bases of all the feathers brown. The bill and the feet are also black; the tail is rounded. The female has the ground colour of the plumage on the upper part blackish brown, with the tips of the feathers slate-grey, more or less intense, according to the age and condition of the bird. There are also blue spots on the back of the neck and various other places, and the middle of the back, the rump, and the belly, are often entirely blue, but never of so brilliant a tint as the same colour is on the male.

*EDOLIUS BALICASSIUS*. This species was named and described by Latham as a crow. Like the former, it is a native of Java: its length is about ten inches. The bill and feet are black, and the plumage also is black, with green reflections, which are very rich and brilliant on the upper part. The tail of this species is forked. The colour of the female differs from that of the male only in the black being less pure and intense, and the reflections less brilliant. This species is much on the wing and very noisy, while the depth of its black colour renders it very conspicuous. On these accounts it is one of those which are pre-eminently styled devil's birds. We believe the Malays have some superstition about it, and reckon the detention, and especially the killing of it, a certain means of getting bad luck.

*EDOLIUS ÆNEUS*. This species has been obtained from the continent of India, and there are some doubts whether it may not be the female of another species, as all the specimens which have come to Europe have been females. The brilliant reflections on the female of this species form rather an exception to the general character. The whole upper plumage is black with very brilliant and iridescent reflections of bronze green. The under part, the bill, and the feet are dull black.

*EDOLIUS CÆRULESCENS*. This is also an Indian species, by no means rare in many parts of the country. It has been long known to naturalists, and was described by Edwards under the name of the hook-tailed Indian butcher-bird. The length is about seven inches: the bill and feet are brown. The whole of the body-feathers on the upper part are deep black, with reflections of blue and copper-colour; the under part is black, passing into whitish on the belly. The wings and their coverts are brownish black, with a white spot on each of the first and second quills.

*EDOLIUS PLATURUS*. This species is from the eastern islands, though it has been described as an African bird. It is the Malabar butcher-bird of some writers, and the paradise cuckoo of others. These names are, of course, wrong, but from the refundance of them it is probable that the bird is generally distributed over the south-east of Asia. The length, taken from the point of the bill to the extremity of the second feather of the tail, is about eleven inches. The bill and feet are black. The general plumage is black, with iridescent reflections of green, the colour being less intense and the reflections less brilliant on the under side than on the upper. The bristly feathers at the base of the bill are very long and retroflected

toward the forehead, at their points: the tail is much forked, and the two outside feathers are considerably longer than the others, and they are peculiar in their form. The webs on both sides for a portion of the length near the middle, are very short; but beyond this they expand into two palettes or discs, which are turned round partially in a sort of spiral form. It is on account of these flat discs on the ends of the feathers, that this species gets the name of *platurus*, or "flat-tail." It does not appear that this species is found so far inland or northward in India as some of the others.

**EDOLIUS REMIFER.** This species is found in Java and the other eastern islands, and also in India. It is not quite so large as the one last mentioned. The length from the point of the beak to the end of the middle feathers of the tail, is about nine inches. The greater part of the tail-feathers are of equal length, forming a squared termination; but the two outside ones are much longer than the rest, and peculiar in their form, for all that part of their length which they extend beyond the intermediate feathers, they have only rudimental necks; and thus they project beyond the squared extremity of the tail, like two little rods, or spines, tapering off to mere fibres at the points. The absence of the discs at the end of the produced feathers, makes this species to be at once distinguished from the last mentioned one. The reflected colours are also different: the upper colour is black with bright reflections of a very peculiar rust-coloured brown; and that on the under part is dead or flat black, without any reflections. The hairs at the base of the bill are long and velvety, and incline forward at the points. The bill and feet are quite black.

**EDOLIUS LEUCOPHEUS.** This species is found in Java, in Ceylon, and also in India. In its colour it differs considerably from any of those which we have noticed. The general colour of the plumage is one uniform tint of dark leaden grey; and the bill and feet are of the same. The coverts of the wings are blackish brown, and the outer webs of the quills black. The tail is long and much forked. The entire length of the bird is about nine inches. Though more calm in the tints of its plumage, this is one of the most active and graceful on the wing of the whole genus.

**EDOLIUS MASERUS.** This is a native of the shores of Southern Africa. It is between eight and nine inches in length. The general colour of the plumage is black, with much less brilliant reflections than any of the others. The inner sides of the quills are grey for the greater part of their length, and brown at the points. The tail is very slightly forked.

**EDOLIUS FORTIFIRATERS.** This is another South African species, being found not unfrequently near the shores in the colony of the Cape. It is larger than the former one, and more brilliant in its appearance. The length is about ten inches; the bill and feet are leaden black; the general colour is black, with very bright green reflections. A crest is formed by long and straight feathers which rise in front of the forehead, and bend forward over the bill. It is a very handsome as well as a very active species.

**EDOLIUS MYSTACEUS.** This is also an African species, about the same size with the preceding, but it differs in colour and in the situation of the produced feathers. The general plumage is black, with green reflections, not quite so brilliant as those of the for-

mer; but the wings and tail have a shade of brown in them. The bill and feet are also black. There are two tufts of produced hair-like feathers, which form a sort of mustachoes close by the bottom of the gape. The female has some white spots on the belly.

Such are the specimens of this very peculiar genus of birds,—birds which have the general form of the fly-catchers, and the bill not unlike that of the shrikes; but they have not the habits or the colours of either. They are more social, more noisy, and seek their food more by continued flight in the open air. The times when they are understood to be most on the alert, are those when the bees are setting out for their pastures, and again when they are returning home.—They do not confine themselves to bees, however, but are very active in capturing many of the other insects with which the shores and margins of the tropical countries abound so much. They have few or no attractions as cage birds, and they are not at all tempting as game; but still they give a great deal of liveliness to the places which they haunt, and may be considered as forming a feature in the scenery on the tropical shores of the eastern world.

**EDWARDSIA** (Salisbury). A genus of highly ornamental shrubs introduced from New Zealand. Linnæan class and order *Decandria Monogynia*, natural order *Leguminosæ*. Generic character: calyx pot shaped, cut or rent above, remains of the margin five-toothed; corolla standard connivent; keel obtuse, a little longer than the wings; stamens imposed on a discous ring round the germen; style filiform, protruding; pod beaded, square, many-seeded. This genus is nearly allied to *Sophora*, and is what may be called half-hardy. They do well trained to a south wall, if the root be protected in winter. It may be propagated by layers, cuttings, seeds. The latter ripen frequently.

**EEL** (*Anguilla*). A genus of soft-finned fishes without ventral fins, of which the general appearance is so familiar to every body, and so different from that of the majority of fishes, that it requires no particular description. In the articles *ANGUILLIDÆ* and *ANGUILLA*, in their proper place of the alphabet in this work, there will be found some particulars relating to the general characters of the family, and to its subdivision into genera; and under the word *MURENA* we shall give some account of those species which inhabit the sea, and which, independently of the fact of their being salt water fishes, have other characters sufficient to warrant their separation from the fresh water eels, which are the true eels, and to which we purpose to restrict the remainder of this short article.

In many points of view, eels are a highly interesting genus of fishes. They are exceedingly numerous, they are found in almost every part of the world, they are wholesome and agreeable as food, and many of their habits are very peculiar. Nor are they interesting only for the truth, which is now tolerably well established, with regard to all their leading habits, for they are almost equally interesting in consequence of the prejudices on the part of people generally, and the blunders on the part of naturalists, of which they have been the innocent causes.

The serpent-like shape of an eel, and the fact of its living generally at the bottom of the waters, and in mud if possible, caused it to be mixed up with all the prejudices which mankind have entertained against the serpent tribe; and so inveterate appears to have been, and in many cases still to be, this prejudice,

that even Pennant, whose industry is at least a strong ground of palliation for his blunders, appears not to have been able to divest himself of the notion that there is a spice of the serpent in the habits and disposition of the eel, as well as a slight resemblance in the shape. It may not be amiss to give the substance of the passage, as containing a very remarkable admixture of truth derived from observation and error begotten by prejudice. "The eel," says Mr. Pennant, "is singular in several matters relating to its natural history, and in some respects borders on the reptile tribe; the eel is known to quit its element, and during the night to wander along the meadows, not merely for change of habitation, but also for the sake of prey, feeding on the snails in its passage; during winter it beds itself in the mud, and continues torpid like the serpent tribe, is very impatient of cold, will eagerly seek shelter in a wisp of straw flung into a pond in severe weather, and which has sometimes been practised as a method of taking them." This does not go quite the length of the common saying, which however is applied ironically to persons who are not over wise, that they would answer well for "catching eels among green barley;" though Albertus goes the length of saying that he had actually seen them leave the water and take up their abode during the night in a hayrick, where, however, they did not find a place of safety, inasmuch as they died of cold before the morning. That eels do avoid the colder parts of the water at certain seasons of the year is no doubt true; but, as we shall see afterwards, the reason of it is physiological rather than a mere avoidal of the cold for their own personal comfort. Indeed if some of the reports, which are stated as from personal observation be true, eels are capable of being frozen up during the cold weather. This, though singular, must not be regarded as an impossibility; for it is very probable that eels pass the very cold weather, at least in cold countries, in a state resembling hybernation. The account of the freezing of three eels was given by Mr. Swallow, who was a good many years ago British consul-general in Russia. "Having," says he, "occasion to go from Petersburg to Moscow, where eels are a great rarity, he ordered some to carry as a present; upon being taken out of the water, they were thrown upon the ground to be frozen, and soon appeared quite dead, and almost a piece of ice; they were then packed in snow, and when he arrived at Moscow, which was four days after, the eels being put into cold water, and so thawed, discovered gradually signs of life, and soon perfectly recovered."

The supposed relationship between eels and serpents very naturally led to the imputation of the former of many of the fables related of the origin of the latter. It was a very general belief, in ancient times, that serpents of the most deadly venom were bred out of the mud or slime of the Nile and other flooding rivers of warm countries, when the drought set in and the waters subsided, leaving a sediment upon the banks, replete certainly with the germs of small life of various kinds, but quite incapable of itself of originating the most tiny insect. It was observed also that other poisonous reptiles brought forth their young alive; and the two characters, though the one was purely fabulous and the other real, were jumbled together in the supposed production of eels. It may not be amiss to quote from a very impartial compiler an abridgment of those opinions, the more so that some of them have been maintained by writers on natural history,

otherwise judicious and deserving, and that down to the present time; for it is only within these few years that Mr. Yarrell, whose researches have cleared up many important points in the economy of the animal kingdom, and especially in that of fishes, demonstrated in the most clear and conclusive manner that the generation of these fish takes place in the same way as that of all fishes which are very prolific, namely, by spawning. "The ancients," says the account which we quote, "adopted a most wild opinion about the generation of these fish, believing them to be either created from mud, or that the scrapings of their bodies, which they left on the stones, were animated and became young eels. Some moderns gave into these opinions, and into others equally extravagant; one in particular gives instructions for producing them by art:—'Cut up two turfs covered with May dew, and lay one upon the other, the grassy side inwards, and thus expose them to the heat of the sun; in a few hours there will spring from them an infinite quantity of eels; not imagining the possibility of water being supplied with fish, by the conveyance of the spawn by aquatic birds of prey, in a similar manner as vegetation is spread by many land birds. As to their immediate generation, it has been amply proved to be effected by the ordinary course of nature, and that they are viviparous. Many persons have convinced themselves of the fact, by opening and taking from the eel a small soft whitish substance knotted curiously together; upon being put into water this has separated, and the young eels were perfect, and, though not bigger than a small thread, have swam about; this discovery always took place the end of summer or the beginning of autumn, and has been adduced as a confirmation of their going down to the salt water to spawn. Those that remain in the rivers, or that have been carried by floods into rivulets and ditches, of which some are to be found at all times, produce the young in the same way." The catalogue of absurdities with regard to the production of eels might easily be extended to a very considerable length; and though it is not our intention to record the details of these, yet their number and the inveteracy with which many of them are believed, even in our own times, render it necessary to take some notice of them. When it is found that prejudices of this kind are general among many nations, and continued through the lapse of ages, it showed that there is something like truth in the foundation of it, and these are precisely the cases in which writers, who address themselves to the great body of the people, should exert themselves to the utmost in removing the ground of the prejudice. One of the most singular errors of public belief, with regard to the production of eels, is that they are formed of the hairs which drop from the tails of entire horses which find their way into the water. The hair, according to the belief, is first converted into a species of *Filaria* or thread-worm, the *Gordius aquaticus* of Linneus, which is exceedingly common in small brooks and pools, especially after summer showers. This animal is not thicker than a moderate sewing thread, and about four or five inches in length, swimming about with considerable activity, and often twining its body into very curious knots. It belongs to the leech family, or rather is closely allied to them; for though its body is formed of rings, it is not extensible and contractile, like that of the leeches, neither is it provided with any sucking apparatus, so far as is known. Yet this creature is, in many

parts of the country, believed to be in due time transformed into the common eel, and sometimes also into the lamprey or lamprey, a belief in which there is of course no foundation. Even this is not the only method in which, according to the belief of those who have some pretensions to science, *filaria* have been considered as young eels. The belief of eels bringing forth their young alive was very general till more than one-fourth of the present century had elapsed; but though it was tacitly concluded to be true, nobody was in possession of very decided evidence of the fact, as indeed they could not, the fact itself being the other way. Eels are infested with many kinds of *entozoa* or worms, which feed upon the substance of their intestines. Of these, the most conspicuous is the *Echinorhynchus tereticollis*, which insinuates its head very often through the internal and middle coats of the intestine, and there remains with the head forming a round lump visible externally, and the body floating in the vessel. These are generally whitish or yellowish in the colour, and are certainly very unlike in shape to eels in any stage of their growth; but still they have been described as the young of the eel in a certain stage of their growth. A more probable species of young eel, in progress for delivery alive, was, at least in so far as shape was concerned, found in the intestinal *filaria* which infest the eels, and are often found free in the vessel, and moving about with considerable activity, and if in a fluid with something like an eel-like wriggle. These were very confidently regarded as being young eels; and as the sexual differences of the fishes had not been attended to, the eel was set down as an animal of double sex, bringing forth its young alive.

In the foundation of this opinion, which was stated with the greatest confidence, there was one little matter which might have prevented the error. Those living creatures were invariably found in the digestive organs of the eel, and never in any separate cavity or viscus, which appeared to be prepared by nature for the bringing forward of a viviparous progeny, or even maturing an oviparous one, such, for instance, as the roe of a fish. Now, though there have been instances of extra uterine impregnation, and also gestation, so far at least in even what are considered the more perfect of the warm-blooded animals, these have always been properly considered as monstrosities or departures from the course of nature, instead of being parts of that course. Nor even in the most simply organised living creatures with which we are acquainted, is there any instance of the young being produced in the stomach, or in any part of the whole intestinal canal. Indeed, if we consider for a moment, we may see that the natural functions of this canal are directly opposed to, and therefore incompatible with any species of reproduction. The whole of the digestive apparatus is a decomposing apparatus in respect of every thing received into it; and, in animals of vigorous stomachs, there have been many instances of partial decomposition of the viscus by its own action in cases of great privation of food. It is true that *entozoa* breed and live there, and that though we know but little of the peculiar mode of their production, *filaria* are apt to breed in the cerus cavities of very many animals; but animals which breed and live in such places, unless they undergo transformations afterwards, are not fitted for living any where else, and we could not by possibility imagine them to be so metamorphosed as to assume the habits and per-

form the functions of those very animals on which they are parasitical. If these considerations had been duly weighed, they would have been decisive against the possibility of eels being viviparous; but it has often happened in natural history, that a theory founded upon even the most ridiculous prejudice, or even upon a description attempted to be made fine by some one possessed of more words than understanding, has been maintained so resolutely as to defeat even the direct observation of the maintainer, to say nothing about the general analogy of nature, in which certain definite functions always accompany a certain definite structure.

The peculiar migrations of eels, which are of too striking a character to have been overlooked, even at periods comparatively remote, might have led to sounder conclusions with regard to the mode of their reproduction; but for a very long time no attempt was made to generalise what was observed in this way, or even to ascertain for what purposes fishes, which at other times remain so silently at the bottom of the waters, undertake journeys of very considerable length, and pursue them with a determination rarely equalled by any other race of animals. Here, also, a general analogy of nature was lost sight of, which, if followed out, would have certainly led to the facts of the case. From time immemorial, it has been well ascertained, that in the autumnal months, taking October as the average of the British islands, eels which have access to the streams of rivers, invariably descend towards the sea. In ponds and stagnant waters which have no permanent outlet, the autumnal migration does not, of course, take place to the same extent; and yet if the pond is not too far removed from running streams, it is highly probable that some portion of the eels make their escape from it during the autumnal rains. It seems, too, that those which do not so escape, feel no small inconvenience from the cold of shallow ponds, if the winter is at all severe. We have understood from what we consider as being undoubted authority, that in some ponds of considerable extent, but no great depth, in Beddington Park, near Carshalton, in the county of Surrey, the eels have not this means of escaping in the autumn; and that not many years ago, a young man lost his life from cold, in consequence of catching eels in those ponds during the severe weather of a rigorous winter. He used to break a hole in the ice, and descend nearly up to his middle in the cold water; and the eels, appearing to be attracted by the warmth of his body, came clustering round his feet and legs in great numbers, so that he could take them with the hand in almost any quantity, using a bit of sand paper to give firmness to his grasp. He found this kind of sport so very successful, that he pursued it, until the water, from its cold, had so severe an effect upon his own system, that he died. This is a very curious fact in the natural history of eels, and shows that, even if they can, as alleged in the case of the Russian ones, endure being frozen without loss of life, they are very sensitive, even to a very moderate degree of heat, when shallow water is so far cooled down as to be frozen over on the surface. In the deeper lakes, which do not freeze even in our severest winters, and from which an outlet is not easily found, it is probable that the eels find a winter asylum in the deeps, where they in all probability bury themselves in the mud during the inclement season; and it would be an interesting problem to ascertain whether those eels which are cut off from regular migration

breed as often and are as prolific as those which have free access to the estuaries, and can pursue their autumnal journeys without much difficulty; but as it is difficult to reach eels in those deep waters, the point is one which cannot be settled without the most careful observation.

The annual descent of the river by eels, at nearly the same season when salmon and other fishes which spawn inland are ascending, has been ascertained in very many parts of the country; and we believe it is most remarkable in rivers which pass through no lakes of very considerable magnitude, or in those which flow by short courses from lakes to the sea. The river Ban, in Ireland, which flows from Lough-Neagh to the North Sea, has been long famed for its eel fisheries. Many years ago the fishery of this river is represented as having let for one thousand pounds a-year; eels of the weight of nine or ten pounds being sometimes taken, and the time of finding them in the river, at least in numbers, was during the autumnal rains, while they were descending; and we believe that, long before the subject was thought of by professed naturalists, the fishermen on the Ban were in the habit of considering, as a matter of course, that the eels descended to the sea in order to spawn, in the same manner as salmon and trout ascended the river for the same purpose. Nor was this all that was known of the true history of the fish by those fishermen, for they were in the habit of suspending ropes of straw across the falls and rapids, in order to assist the young eels in their ascent during that part of the summer when this movement takes place.

On smaller rivers, the greater part of the water of which, except during floods, is taken to the mill courses, the millers have long known how to carry on a very successful eel fishing with very little trouble during the autumnal ascent. There is one stream in Forfarshire where we have seen this fishing carried on to a very great extent. This stream is the Vinney, which flows eastward and enters the British sea in the bay of Lunan, between Arbroath and Montrose. The principal stream originates in, or passes through, a number of small lakes, containing great quantities of peat and marl, and apparently particularly favorable for the pasture of eels, which are found in vast numbers both in those lakes and in the pools of the rivulets which discharge their waters into them. Marvellous stories are often told of the size and formidable character of eels which are obtained in those small lakes, when partially drained, in order to obtain the marl by digging, and not by drudging; and we have often heard of eels ten or twelve feet long, as thick as the calf of a man's leg, and capable of leaving the impression of their bite in a steel spade. Of course these are exaggerations, but they serve to show the district alluded to is not only a great eel country, but a country of great eels. Well, in autumn, especially when it is moonlight, for the eels are understood to like to see their way, though night wanderers, the millers open the sluice of the mill pond, or rather it does not require to be shut during the autumnal rains, and place a large basket to receive all the water of the "off-shot," the whole being stopped and turned into that, at the point where it would descend on the wheel. In the morning it is no uncommon thing to find a hundred weight of eels, or even more, in one of these baskets; and, we believe, that it is either a point of justice or of honour among the millers, that they shall all take their turn

during the migration, so that he who lives farthest up the water-way may not enjoy a monopoly to the injury of the rest.

The accounts which have been long known of other places are nearly the same. In Scotland, in the neighbourhood of Linlithgow, is a considerable lake, in which great quantities of eels are caught by hooks and lines during any of the summer months; but the principal fishing is in the month of October, when it is found that the eels, directed by natural instinct, discover an irresistible propensity to issue from the loch by the passage through which the water flows from it to the sea. In October, the person who rents the fisheries puts into that passage a kind of chest, so formed as to allow free passage to the water, while it stops those eels that exceed a certain size. This chest is every morning emptied of its fish, which are sometimes in such abundance as to require carts to carry them away. This fishing continues about a month, before or after which time few or none can be so taken: the chest is then removed, and the passage left free.

In Wiltshire, about Warminster, where the rivers are smaller and more rapid in their course than in many other parts of England, the mills placed on the streams are numerous, and the water is carefully directed into one channel. The persons possessing these mills having discovered that numbers of eels go down the river during every flood happening in October, have devised a box which they call an eel-grate; this is placed in a convenient part of the river, and thus great quantities of eels are caught. They also find, that no eels worth mentioning can be taken in this way at any other season of the year.

Whether the eels thus caught in descending the river are near the breeding time, was not for a long time ascertained, though the fact is now established that breeding is the grand purpose for which the descent takes place. It has been clearly ascertained by repeated observations, the accuracy of which cannot be questioned, made in very different parts of the country, that eels invariably descend the rivers to the lower estuary, wherever such a purpose is practicable. The fact that they were found in vast numbers in the ooze and sludge, or sand of such places, was well ascertained for many years previous to the time that naturalists began to inquire what brought them there. Sludgy mud, or what is usually termed a fat beach, from which the tide ebbs to a considerable distance, but which is still full of stagnant pools and runs of water, even at the ebb, are the favorite places for them. There they lie during the cold weather, buried under the surface, and matted together in clots; and there are many places where great numbers are caught during the winter between the prongs of barbed spears, which are pushed along the soft sludge until it is ascertained that they have taken a sufficient load. This is, we believe, very extensively practised in the bay of Southampton, and at the mouths of many of the moderately sized rivers of other parts of the south of England; but though not unknown in the northern parts of the country, it is carried on less extensively there. The fact is that, in the northern parts of Britain, in Scotland especially, the prejudice of the people runs very strong, not only against the form of the eel, but against the quality of its flesh as an article of food. It may be that, in the latter respect, the eels of cold, and especially of moss-tinged waters, are much inferior to those of clear streams, or of those balsamic waters which acquire a golden, or, at all

events, an amber-coloured tinge, from the great quantity of rich loam in a state of very minute division, which they hold in solution. The substances upon which eels feed acquire a very remarkable difference of character, from difference of water and its deposits; and the worms which are brought in by the streams on pastures composed chiefly of sand mixed with peat earth, are so pale in the colour, so hard and unpalatable, that even the hungriest trout in better places spurns them as unworthy of his palate. How much there may be in this, we do not know, but certainly eels are held in small estimation in the north, and even discounting their serpent form, they are regarded as far from wholesome. In some places, indeed, they rate at what is usually considered "cat's price," that is, they are worth nothing but the skin; but in proportion as the flesh of the animal is despised, it is probable that the skin rises in value. The bare-footed cow-boys of the Scotch hills may run with any velocity they choose across the most stony pastures without breaking or injuring a single toe, if each ankle is defended by a circular amulet of eel-skin; and if even in her tender years a girl goes to the severe labour of the harvest field, her feeble arm never experiences the very painful sickle sprain if she has it defended by a bracelet of the serpent-looking fish. Nay, in the case of any of these contingencies having already happened for want of this invincible skin, its curative power is so great that it will not only take away the grief of the hurt instant, but effectually cure it in briefer space, and with far more certainty, than the whole fraternity of body curers, with the entire *materia medica* to boot. These superstitions point to some interest about the fish, which is, no doubt, in part owing to the obscurity of its manners; and had we not so many proofs that prejudice bewilders and leads astray in proportion to the depth of the impression which it makes, we might be tempted to suppose that the attention which the eel commands would long ere the present day have led to a knowledge of its economy and manners.

That the eels in their annual migrations "descend upon the heat," or that they seek water of a higher temperature than that from which they retire, is not only probable, but certain, though the ultimate purpose which this migration answers in their economy is physiological, not physical. In all the movements in animals, indeed, whatever may be the ultimate purpose for which they move, the primary cause, as affecting themselves, is physical; and it cannot be otherwise: for to suppose that they are capable of looking forward to the physiological result, would be to suppose them endowed with forethought plan, and, consequently, with the faculty of reasoning upon cause and effect. As regards the animal, the movement, whether to a greater or less distance, goes not beyond the fact which we observe; and the finding out of the physical purpose which this movement answers, is the business of man, the observer, and not of the animal observed.

We know that, in consequence of a slight compenetration, or lessening of the total bulk taking place, where the fresh water of a river blends with the salt water of the sea, there is constantly a small portion of heat given out in the brackish water which the mixture forms, and because of this giving out of heat the brackish water is warmer than either the fresh or the salt. This fact tells not only in the collection of fishes of various kinds to this part of the waters, in

order to bring their roes and milt to maturity, but also in the superior vigour of all vegetables on the banks, along that portion of the tidal estuary in which this brackish water plays backward and forward, at least to some extent, with the ebb and flow of the tide. There is another reason which not only brings fishes, but, in the winter season, the aquatic birds to these places of the rivers. It is between the river and the sea that all the light and loamy, and consequently rich matters which the rivers bring down, are deposited in the channel; for it is only the particles of washed sand which have sufficient firmness and weight for being carried out to sea, even to form a bar in the salt water along the river's mouth. Now the quantity of small animals, worms, mollusca, small crustacea, insects, and others which are produced in those rich deposits, and even brought down to them by the fishes, is very great, and forms an abundance of food, both for the fry of fishes, and for the aquatic birds. But though this is somewhat different from the mere fact of the greater heat of the water at such places, it co-operates in producing the general result.

It is not for the mere purpose of depositing their spawn that fishes resort to this portion of the waters, but rather for the purpose of bringing it to maturity, so that it may be fit for being deposited. In this we have a means of judging of some very important differences in the habits of fish; and there is, perhaps, none more worthy of attention, at least in the British islands, than salmon and eels. The salmon is a fish of the free waters, seldom lying at the bottom, even for the purpose of repose, and it swims with greater velocity than almost any other river fish, though the strength of its exertion soon exhausts it. The eel, on the other hand, is a bottom fish, rarely if ever coming to the surface. It is comparatively slow in its motions, but capable of very long continuance; and, indeed, in all things it is a fish of very great endurance. The salmon spawns in the latter part of the year, before the frosts set in, and while the inland waters in the brooks and shallows, having been acted on by the sun of the whole season, are comparatively warm; therefore the salmon ascends the estuaries during the time of the growth of the spawn, and that is deposited as far in the interior as the fish can reach. The eel, on the other hand, spawns in summer, earlier or later, according to the latitude, and the character of the river in whose estuary the operation takes place, being in May in the rivers of the south of England, but not earlier than June in the more northerly parts of the country. These facts have been ascertained by actual observation of a number of eels of both sexes, in the progress of the spawn to maturity, in its fully matured state, when in the act of shedding, and when immediately shed, in the last of which cases, eels follow the general law of all fishes, and are quite exhausted and unfit for food. In what way the spawn is deposited has not been ascertained; but from the habit which the animals have of burying themselves in the mud, it is probable that they bury it to such a depth in the ooze of the shallows, as that it is not disturbed by the agitation of the waters. It is known, however, to be very abundant in quantity, and, indeed, there is, perhaps, no fresh water fish so prolific as the eel; and for this reason, it might be worth while to attend to the artificial rearing of eels more than has hitherto been done. It is partly with a view to the breeding of those fishes for economical purposes, that the ascertaining of the mode in which they breed is a

point of so much importance ; for until this fact was made out, it is evident that any attempt to treat them artificially could be no better than mere guess-work. In all fishes, indeed, which are reared in ponds or other artificial waters for economical purposes, it is absolutely necessary that the economy of the fishes should be well understood.

How the eels dispose of themselves after spawning time, whether they ascend the rivers again during the same season, or remain a season or more in the brackish water, or in the lower part of the river, in order to recruit their strength, has not been ascertained ; though there is some reason for thinking that they do not breed every season ; and, indeed, this is, probably, the case with a great number of fishes, especially with those which are migratory in the breeding season. Some of the large eels have been observed ascending the currents of rivers ; but they have not been so observed in any thing like such runs as on their descent. This might, perhaps, be expected, at least in might be so, from the analogy of other fishes. In the salmon, for instance, we know very little of their descent to the sea, after spawning in the inland waters, though there is no doubt that, in consequence of their numbers, in rivers favourable to them, many must descend, notwithstanding the numbers that are taken. They appear, however, to get to the sea in the speediest manner possible ; and for this purpose they keep the middle of the stream, and do not, perhaps, come so near the surface as when they are on their ascent. In ascending the estuaries and larger rivers, the salmon are generally at no very great distance from the shores, as they have there the advantage of the eddy water, against which they can make way more rapidly than they could do against the stronger current in the main channel of the river. One would naturally suppose that the eels would also make their ascent near the shores, to have the advantage of the eddy, and probably this is the case with the old ones, as it is known to be with the young. It is not near the banks that the eels are taken in such numbers while descending the streams, it is where the whole of the current can be received into a net, or basket, which allows the water to pass through, but retains the fish.

But though the time and manner of the eels which have spawned ascending the rivers, has not yet been clearly made out, the case is different with the young fry. In the larger rivers, and especially in those which flow through places so rich in small particles, as to have their waters generally tinged, the march even of these is not seen ; but in the clear rivers they have been observed, and observed in such numbers as to demonstrate that the fishes spawn in the lower parts of the rivers, and also that they are exceedingly prolific. Unless when swollen by rains, the river Dee, which empties itself into the sea at Aberdeen, is remarkable for the transparency of its waters, and perhaps there is no stream of equal magnitude in the island, where the movements of fish can be better observed. At the season when the salmon are ascending, one may stand on the old bridge and see them moving up the stream in a continued shoal, which continues for a long time. In the same river the ascent of the young eels from the sea has been described by an eye witness in the following terms :—" I know, and it has been observed by others, that in the month of June, yearly, immense swarms of young eels make a progress from the lower part of the river towards the

higher, with a quickness and unremitted assiduity that are surprising. This phenomenon was remarked in the river Dee, in Aberdeenshire. The eel is a fish that seems (unlike the trout) to dislike running streams, and therefore avoids that part of the river where the current is strong. It had, probably, been this circumstance that induced them, in the rapid Dee, to direct their progress only along the edges of the river close to the banks. A line followed the windings of the river, being often suddenly deflected by stones or other interruptions without any breach of its continuity. This line having frequently caught my eye, my hand was put into the water to touch the line, with a view to examine what it was : the line became discontinued when my hand approached ; but it united again as soon as my hand was withdrawn. This induced a nearer examination ; and I then perceived, with astonishment, that this line was formed by a series of small eels, moving forward with great celerity. These eels did not exceed half an inch in length, but were in all respects perfectly formed like the common eel. The line might, perhaps, on an average, consist of from twenty to thirty in breadth, and the individuals being in different degrees of forwardness, and close to each other, made the line uniform. The progress with which they advanced was not less than four miles an hour ; and this continued for eight days and nights together ; and there was no apparent diminution of it when I left the place. There was a similar line on the opposite side of the river. The water in which they floated at the place where I observed them was, in general, about two or three inches deep."

In the lower part of the Thames, though that is a good eel river, the motions of the young eels upward cannot be so easily observed, because of the quantity of mould which is generally suspended in the water. This circumstance is, however, as favourable to the breeding and security of eels, as it is unfavourable to the observation of them. There is one place in the river where, however, they may be seen in great numbers, and this is at Teddington lock. The river is, generally speaking, rather low at the time when they reach this obstruction on their passage outward ; and they have been observed climbing up not only the weir, but the wooden posts with very considerable adroitness, so as to gain the water above. We believe that those climbings are generally performed during the night, and consequently, they are not observed to their full extent, though when the sky is overcast, considerable numbers of them make their passage upward during the day ; and it is on these occasions that they are seen, and seen in sufficient numbers to prove the fact in this river, as well as in others.

To what height an eel can climb in making its way up the rivers has not been ascertained ; but as they are found much higher up than salmon, it is probable that they can scramble up the rocks by the side of waterfalls, which are too lofty for the leap of that active fish. Indeed, there are some well-authenticated instances of eels making their escape from ponds, either where there was an overstock, or in consequence of the natural instinct of getting to the brackish water, by climbing trees, especially weeping-willows having the points of their pendent branches in the water of the pond. The eels ascend those branches pass the bole of the tree, and then descend the branches on the other side. If they find water at or near the

extremities of those branches they soon get into it, and make their escape; but they frequently ascend, and are found crawling and wriggling about in the meadows, where also they can move to a considerable distance, especially if there are little pools, which serve them as a sort of inns, or resting places, on their way. In consequence of this power of climbing, and also of moving over land, eels are much more capable of distributing themselves generally throughout all the waters of humid places, than perhaps any other kind of fish. On these migrations, and also when they are ascending the shallows near the banks of the rivers, vast numbers of them are seized by herons and other wading birds. Indeed, where they are numerous, eels are the favourite food of the heron; and after a summer shower has favoured their ascent into the upland brooks, herons may be observed watching for them with great assiduity, in places where there is no heronry within many miles. See the article HERON.

In countries farther to the south, eels are still more abundant than they are in any part of Britain; and in those places they form no inconsiderable part of the food of the larger wading birds, such as cranes and storks. They are exceedingly numerous in the river Po, as the lagoons and banks at the mouth of that river, on the latter of which the city of Venice is built, are peculiarly favourable as breeding places for them. In no place, however, is there any danger of confounding fresh water eels with those which are permanent inhabitants of the sea, and never ascend the fresh waters, though, like the others, they appear to resort to the shallows and brackish waters for the purpose of breeding.

The general characters of the whole of the eel family, which is a very natural one, are, the body elongated, the skin very thick, generally without any scales, and rendered exceedingly slippery, by a mucous secretion; their intestines are without any cæcum, and the greater number of them have air bladders. The true eels have the pectoral fins very far forward, and the gill openings, which are very small, placed immediately under those fins; the stomach, or long cul-de-sac, and the intestine, nearly straight; the air-bladder very much elongated, and with a gland placed at the middle of its length; and they have the dorsal fin beginning at a considerable distance behind the pectorals. The fresh water eels have also the upper jaw shorter than the lower one, while the sea eels have the shorter lower than the upper, and in them the dorsal fin begins much nearer the pectorals than in the fresh water eels.

This difference of structure in regard to the commencement of the dorsal fin, shows that the two are fitted for progressive motion of a different kind. The pectoral fins in the fresh water eel keep the head steady to its course; and the portion of the back which is without a dorsal, obeys the motion of the head, so that the fore part of the fish can proceed steadily in a straight line, at the same time that the body, behind the commencement of the dorsal, performs those motions which are necessary to project the whole forward. In both the sea and fresh water eels, the dorsal and anal fins meet at the extremity of the tail; and thus the whole of the posterior part of the body is a sort of paddle, by means of which they work themselves along, something in the same manner as a boat is worked along by sculling with one oar, worked right and left across the middle of

the stern. In the British waters there are, at least, two species of fresh water eels, which are distinguished as the *sharp-nosed eel* and the *broad-nosed eel*. The colours of both these are nearly the same; but the broad-nosed one is rather thicker in proportion to the length, and has the head larger and the gape wider. It is also said to be fuller of flesh and more juicy than the other, though this, no doubt, depends in a great measure upon the season at which it is taken, and the water which it frequents. There is nothing, however, so strikingly different in either the appearance or the habits of those two species, as to call for any particular description of them as distinguished from each other.

The great interest of these fishes is in the peculiarity of their manners, and the mistakes and absurdities which have so long prevailed on the subject of them. There is, indeed, another point of view in which they are worthy of some consideration: it is probable that before many years have elapsed, eels may be the only fish obtainable in the lower parts of those rivers where our great manufacturing towns are situated, and where the refuse of gas-works, and countless other impurities are continually discharged into the water. Those impurities generally float on the surface, or, at least, very near it, and thus they are fatal to salmon, trout, and all other fishes which swim near the surface; but if the water is of any considerable depth, the eel is sufficiently far down to breed in safety.

EGLANTINE is the *Rosa eglanteria* of Linnæus, a wild species of rose common in many parts of Europe. A bramble introduced from New Holland in 1825 is also called eglantine.

EGYPTIAN LOTUS is the famous *Nymphaea Lotus* of Linnæus, a magnificent aquatic plant, abundant in the Nile, and in most of the tropical and other rivers of Africa and Eastern Asia. The leaves are ample, petlate, and mostly float on the surface of the water; the flowers are large and showy, and the main stems of the plant creep in the mud, are jointed tubers and esculent. The canals in China are in some places literally choked up by this plant, but it is in that empire an inexhaustible source of food for the poorer inhabitants, who use the tubers as potatoes are used in Europe. The order *Nymphaeaceæ* is pretty generally distributed. The *Nelumbiums* of Africa and China, the *Nymphaeæ* (water-lily) of Europe and America, and the *Euryale* of India, are all included in the order. The *Nymphaea nelumbo*, now called *Nelumbium speciosum*, was first flowered in England at Bulstrode, the seat of the Duke of Portland, about the year 1790.

EGYPTIAN THORN is the *Acacia vera* of Willdenow, an ornamental tree, native of the northern parts of Africa.

EHRETIA (Linnæus). A genus of tropical trees and shrubs, belonging to the fifth class of Linnæus, and to the natural order *Ehretiaceæ*. Generic character: calyx five-toothed, or cut irregularly; corolla bell or funnel-shaped, limb five-cleft; stamens having awl-shaped filaments inserted in the tube; anthers two-lobed at the base, two-celled, and protruding; style divided, bearing acute or obtuse stigmas; drupe bony, two-seeded, sometimes four-seeded; embryo inverted. These exotics thrive well in the greenhouse, and are easily propagated by cuttings.

EHRETIACEÆ. A natural order of dicotyledonous plants, containing only a few genera and

species. By many authors it is considered as a section of *Boraginæ*, from which, however, it is distinguished by its terminal style proceeding from the apex of a perfectly concrete, four-celled ovary, and its berried fruit. By others it is included under *Cordiaceæ*. It bears an affinity to *Heliotropiceæ*, from which it differs chiefly in its succulent fruit.

Its essential characters are: calyx inferior, five-parted, with an imbricated æstivation; corolla monopetalous, tubular, with as many segments of its limb as the calyx, and also with an imbricated æstivation; stamens alternate with the segments of the corolla, and equal to them in number, arising from the bottom of the tube; ovary simple, two or more celled, seated in an annular disc; stigma simple, two-lobed; fruit drupaceous, with as many stems as there are true cells of the ovary; seed suspended, solitary; embryo in the midst of their fleshy albumen; radicle superior.

The plants belonging to the order are trees or shrubs with a harsh pubescence, simple alternate, exstipulate leaves, and corymbose flowers. They are found in tropical regions in both hemispheres, and are not distinguished for any important properties. The chief genera are, *Ehretia*, *Tournefortia*, *Rhabdia*, and *Bourveria*.

The root of *Ehretia burifolia* has a sweetish and somewhat warm taste, and is used in India as a tonic and alterative in enfeebled constitutions. By the Mahometan practitioners it is considered an antidote to vegetable poisons.

**EKEBERGIA** (Sprengel). A tree from the Cape of Good Hope, belonging to *Decandria Monogymia*, and to the natural order *Meliaceæ*. Generic character: calyx four-cleft; petals four; anthers sitting within an annular disc; style filiform, stigma headed; berry round, containing four seeds. This genus is placed in the class *Monadelphica* by Sprengel; is propagated by cuttings, and treated as a greenhouse plant.

**ELÆAGNÆ**—the Oleaster family. A natural order of monoclamydeous dicotyledonous plants, containing five or six genera, and upwards of twenty known species. By its apetalous flowers, definite erect ovula, tubular inferior calyx, and leprous leaves, this order is at once distinguished from *Proteaceæ*, *Thymelææ*, *Santalaceæ*, and *Combretaceæ*, to all of which it bears an affinity.

Its essential characters are: flowers diœcious, rarely perfect. In the sterile or male flowers, the calyx is four-parted; stamens three, four, or eight, sessile; anthers two-celled. In the fertile or female flowers, the calyx is inferior, tubular, persistent; the limb entire, or from two to four-toothed; ovary superior, simple, one-celled; ovule solitary, ascending, stalked; stigma simple, subulate, glandular; fruit crustaceous, enclosed within the calyx become succulent; seed erect; embryo straight, surrounded by a very thin fleshy albumen; radicle short, inferior; cotyledons fleshy.

The plants belonging to this order are hardy trees or shrubs, covered with minute silvery scales, having alternate or opposite entire leaves, and axillary, often fragrant flowers. They are found scattered over the whole northern hemisphere as far as the equator. A few inhabit China and Japan, and the remainder Europe, North America, Guiana, and the East Indies. They are not known south of the line. Many of them furnish edible fruits and astringent barks. The chief genera are, *Elæagnus*, *Hippophæ*, *Shepherdia*, and *Com*.

The genus *Elæagnus*, or oleaster, so named from its resemblance to the olive tree, furnishes several species, some of which are hardy, and cultivated in our gardens. *Elæagnus angustifolia* is a low tree with elegant silvery leaves and yellow flowers, which emit a strong scent, especially at night. *Elæagnus Orientalis* yields a large fruit, which is used in Persia as an article of dessert under the name of *Zimzeyd*. *Elæagnus arborea* and *conferta* also yield fruits which are eaten in Nepal.

*Hippophæ rhamnoides*, common sawallow thorn, or sea buckthorn, is found on sandhills and cliffs on the south-eastern coasts of England. It is a thorny shrub, four or five feet high, frequently cultivated in gardens on account of its silvery leaves. It bears a bright orange berry, which is sometimes preserved and eaten, more especially in Sweden and Tartary. It is used by the fishermen of the Gulf of Bothnia to impart a grateful flavour to fresh fish. The whole plant may be used to dye yellow.

**ELÆIS** (Jacquin), is a palm indigenous to South America, and from the fruit of which an oil is expressed; hence it is called the oily, or olive palm. It belongs to *Diccia Hexandria*, and to the order *Palmæ*.

**ELÆOCARPÆ**. A natural order of dicotyledonous plants, containing six or seven genera, and nearly twenty known species. It is very closely allied to *Tiliaceæ*, from which it differs only in its fringed petals and in its anthers opening by two pores at the apex. By some authors it is included under that family.

Its essential characters are: sepals four or five, without bracteas, and with a valvular æstivation; petals four or five, alternate with the sepals, lobed or fringed at the extremity; receptacle glandular; stamens from fifteen to twenty, filaments short and free; anthers long, four-sided, two-celled, opening by pores at the extremity; ovary many-celled, with two or more seeds in each cell; albumen fleshy; embryo erect, with flat leafy cotyledons.

The plants belonging to this order are trees or shrubs with alternate, simple leaves, and racemose flowers. They are natives of warm climates, and are found chiefly in the East Indies and in South America. Some are also met with in New Holland. Little is known in regard to their properties. The chief genera are, *Elæocarpus*, *Aceratium*, *Dicera*, and *Vallea*.

The species of *Elæocarpus* are in general handsome, and produce showy, fragrant flowers, which are succeeded by an edible fruit. The hard, furrowed stones contained in the pulpy fruit, are manufactured into necklaces in the East Indies. They are sometimes sold in our shops when set in gold.

**ELÆODENDRUM** (Jacquin). A genus of trees and shrubs found in the East Indies, New Holland, &c. Linnæan class and order, *Pentandria Monogymia*, and natural order *Celastrinæ*. Generic character: calyx minutely five-lobed; petals spreading, and broad at the base; stamens alternating with the petals, and fixed on a disk surrounding the germen; style very short; drupe sapless, from two to five-celled, with as many seeds, some of which are often abortive. This genus has been arranged with several other genera by different botanists, but now admitted as fixed by Jacquin. The hothouse species are pretty, and those from New Holland are kept in the greenhouse. They all strike freely from cut-

tings treated in the usual way. The trees are called olive wood.

**ELAPHRIDÆ** (Stephens). A division of the great Linnæan genus *Carabus*, comprising the genera *Notiophilus*, *Elaphrus*, *Blethisa*, and *Pelophilus*. See **CARABIDÆ**. This group is distinguished by the unnotched anterior tibia; the antennæ are short and robust. From the *Cicindelidæ*, with which family they were arranged by Linnæus, they differ in their smaller size, and in wanting an articulated hook at the extremity of the lower jaws. They reside in damp situations, at the margins of streams, &c. The typical genus *Elaphrus* (Fabricius) may be distinguished by the elevated bosses upon the elytra, and by the rounded thorax. There are four or five British species, of which the *Cicindela riparia*, Linnæus, is the type; it is about a quarter of an inch long, and of a brassy greenish colour.

**ELATE** (Linnæus). A species of palm common in India. It belongs to *Monocia Hexandria*, and to its own natural order. It has for a long period been one of our hothouse plants. It thrives best in sandy loam, and requires the warmest part of the stove.

**ELATERIDÆ**. A family of coleopterous insects belonging to the section *Pentamera*, and subsection *Serricornes*, forming with the family *Buprestidæ* (which see), a division under the name of *Sternozi*, and distinguished by having the hinder point of the prosternum produced into a laterally compressed point, so as to be capable of being brought, at the will of the insect, into close contact with a depression in front of the metasternum, whereby, in consequence of the strong muscles with which these parts of the body are armed, the animal is enabled to effect a leap to a considerable height when laid upon its back, whence these insects have obtained the name of skip, or spring-jacks. The body is rather long and narrow, the mandibles notched at the tip, the palpi terminated by a joints larger than the preceding articulations, the joint of the tarsi are entire, and the posterior angles of the thorax are acute.

This is an extensive family of insects, but little diversified in their colours, whence they afford a strong contrast to those composing the other family *Buprestidæ*. The shortness of the legs renders essential some other apparatus, whereby the insects when laid upon their backs may recover their ordinary position. This apparatus is found in the peculiar structure of the parts of the breast noticed above and in the strength of the muscles with which it is furnished. In order to effect these motions the legs and antennæ are laid close to the body in grooves prepared for their reception; the head and thorax are bent backwards, until they reach the plane of position, and then the point of the prosternum being struck with force into the abovementioned cavity, causes a sudden jerk to be imparted to the insect, which has the effect of raising it to a considerable height in the air.

The habits of but few of these insects have been hitherto known. The females are furnished with a horny ovipositor at the extremity of the body, whereby they are enabled to convey their eggs to their destined situation in the midst of rotten wood, &c. De Geer has described one of their larvæ found in such a situation; it is of a scaly texture, and the tail is terminated by a margined flattened plate, of which the sides are notched, and the extremity cut out. The larva of *Elater striatus* devours the roots of wheat, and

occasionally commits considerable devastation. It is this state of the insect which is ordinarily known by the name of the wire-worm.

In the perfect state, the elateridæ are found upon flowers, leaves, and shrubs, and when they are alarmed they fold up their antennæ and legs, and fall to the ground.

Some of the South American species of the family forming the genus *Pyrophorus* (Illiger), are distinguished by the singular powers which they possess of emitting light from two yellowish patches on the sides of the thorax. Of these species, which are named by the natives *Cucuj*, the *Elater noctilucus* is best known, and so strong is the light which they emit, that two or three placed under a glass are sufficient to enable a person to see the time by a watch in the dark; and the females are said to fasten many of them to their dresses as glittering ornaments. According to Brown, all the internal parts of the insect are luminous, but there seems reason to doubt this statement. He likewise asserts that the insect has the power of suspending its luminosity at will. A specimen of this insect which had evidently been conveyed to France in American timber, in which it had undergone its transformations, caused much alarm to the inhabitants of the Faubourg Saint Antoine, in Paris, by flying about the houses, emitting at the same time its light. According to M. Lacordaire, who has observed the insect in its living state, the chief reservoir of this luminous matter is situated on the lower side of the body at the junction of the abdomen and thorax. See an interesting memoir by Mr. Curtis, in the Zoological Journal.

The generic distribution of these insects has, until lately, been but little attended to. Messrs. Latreille, Eschscholtz, and Stephens, have, however, latterly proposed numerous groups, founded upon structural characters, but in their natural history little has been noticed in support of the establishment of these divisions. There are nearly one hundred British species, of which the *Elater (Selatosomus) æneus*, distinguished by its fine metallic tints, the *Elater (Corymbites) pectinicornis*, having branched antennæ, and the *Elater (Ludius) ferrugineus*, being the largest British species, are the most conspicuous.

**ELATERIUM** (Linnæus). A genus of climbing West Indian annuals, bearing large fruit of the gourd kind, and for which they are cultivated there.

**ELATINE** (Linnæus). An aquatic annual genus, containing two or three species, natives of Europe. Two of the species are English plant, and known by the name of water-pepper, or water-wort.

**ELATINÆÆ**—the Water-pepper family. A natural order of dicotyledonous plants, containing only a few genera and species. By many authors this order is looked upon as a section of *Caryophyllææ*, from which, however, it is distinguished by its capitate stigmata, by the dehiscence of its fruit, and the want of albumen. It bears a considerable affinity to *Hypnaceæ*, but differs in having a persistent central axis in the fruit and definite stamens.

Its essential botanical characters are: sepals three to five, persistent; petals three to five, alternate with the sepals; stamens hypogynous, usually twice as many as the petals; ovary with from three to five hypogynous cells, the same number of styles, and small, capitate stigmas; capsule three to five-celled, and three to five-valved; valves separating from the dissepiments which alternate with them; seeds nume-

rous, with a straight embryo, whose radicle is turned towards the hilum; no albumen.

The plants belonging to this order are herbaceous annuals with hollow stems, and opposite, exstipulate leaves. They are found in marshy places in all quarters of the globe. Their properties are not well known. The chief genera of the order are *Elatine*, *Bergia*, *Merimea*, and *Crypta*. The species of the genus *Elatine*, or water-wort, are natives of Europe, and two of them are indigenous in Britain. The *Bergias* are found at the Cape of Good Hope, and in the East Indies, while *Merimea* is confined to South America.

ELDER is the *Sambucus nigra* of Linnæus, a very common plant everywhere. It belongs to the first class of Linnæus, and to the natural order *Caprifoliaceæ*. The wood of this small tree has a very large pith when young, but smaller in old stems, and then the wood is remarkably hard and durable. Water distilled from the flowers is used as a cosmetic, and a kind of wine is made from the ripe berries. There are six varieties in gardens, all of which are increased by cuttings.

ELECAMPANE, is the *Corvisartia helenium* of Merat, formerly the *Inula helenium* of Linnæus. This genus of plants is chiefly European; several of them natives of Britain. They are mostly perennials, bearing yellow flowers, and belong to the order *Compositæ*.

ELEPHANT (*Elephas*). A genus of *Pachydermatous* or thick-skinned mammalia, belonging to that division of the order to which Cuvier gives the name of *Proboscidea*, or animals which have the nose or upper lip elongated, and forming a trunk or proboscis, or other prehensile instrument.

The elephant has but few characters in common with the rest of the order *Pachydermata*; and indeed that order is among the most perplexing in all the mammalia, because the mere thickness of the skin is not a good ground of classification. Thus it is impossible to give, under the title of the order, any general account of all the genera; and therefore it becomes necessary to enter a little more into detail of the characters of each genus.

There is perhaps no animal respecting which less apology is necessary in this respect than the elephant. In point of size and strength, it stands foremost in the whole class of land animals; and though its sagacity and docility have been greatly overrated, it is to a considerable extent tractable, and in so far a sagacious animal. We use these words in an animal sense of course, and not with any reference to docility and sagacity as predicated of human beings; and we may mention that the boasted sagacity of the elephant is vastly inferior to that of many varieties of the dog.

Still the elephant is highly interesting in very many points of view. It has been connected with the power and state of eastern nations from very early times; and before the invention of fire-arms, the elephant was regarded as a very powerful auxiliary in war, and numbers of them were brought into battle, not only in Asia, but in some parts of eastern Europe. Even now the elephant is a useful appendage to an Indian army; but it is chiefly as a beast of burden, in the transportation of artillery, and of baggage which is too heavy for the more ordinary carrying animals. He is also used as an appendage of state, for which purpose himself and the *howdah* or *crib*, which is fastened on his back, are both decked out in the most gorgeous manner. But though the elephant

has thus been made the servant of man for many purposes, almost from time immemorial, it has never been tamed or domesticated in the proper sense of the word. Elephants have never lived in what may be called companionship with society, and under the protection of man, as has been the case with the dog, the horse, and many other animals. There are a few rare instances recorded in which elephants have bred in a state of confinement, but those instances form the exception—the rare exception, and not the rule; and on account of them we cannot venture to say that the elephant has ever been a domestic animal.

There is another point of view in which the elephant is of great interest, especially to those who study the history of nature in its connection, both of place and of time. Of living elephants there are only two species, the Asiatic and the African, though there are several varieties, apparently climatal, of the former one. Of these there is not a vestige in any other part of the world than those in which they are at present found, unless it be the accidental bones of one which has been brought from its native country for the purpose of exhibition, and which, perishing before the establishment of museums in which the bones of strange animals are industriously collected, had been buried by the way side. There are some rather ludicrous instances of the bones of such elephants being dug up, after the appearance of the animal at the place had been forgotten, and gravely considered as the bones of antediluvian or other giants of the human race. The countries in which only the two existing species of elephant are found, all have the tropical character; and as there is no evidence of the animal being naturally out of them, we must conclude that both are adapted to the forests and marshes of those countries, and to them only.

There is, however, a third species of elephant, of which there is no living specimen, though the remains of it are abundant. Those remains are found in very great numbers in the northern parts of Asia, and especially near the shores of the Polar Sea in that quarter of the world; but they are not found to the northward of the Lake of Aral, so that the central plains of Asia do not appear ever to have been an elephant's country; but if we suppose, as is most probable, that the two races were co-existent at some former period, we must suppose that that country, which is in all probability the native one of the horse and the wild ass, formed a sort of natural boundary between the pastures of the southern elephant of Asia and the northern one.

In Europe the remains of this elephant are not so numerous as they are in Asia; but as is the case there, they are confined to the northern parts; and we are not aware that any vestige of them has been found to the southward of that parallel which forms their southern limit in Asia, and which answers to nearly about the middle of France. There are some few of those remains in Britain, though they are not so numerous there as in some places of the continent. This elephant was not, like the two which are natives of tropical countries, confined to the eastern continent, for the bones have been met with in America, though not in any place further to the southward than about the parallel of the south of Spain, which, if we take the two continents according to the average of their present temperature, will answer to about the same limit in point of heat as that which marks the southern boundary of those animals in the eastern

continent. We mention these few particulars in the meantime to show that the elephant has a longer and more interesting tale to tell, than is to be found in all the anecdotes which are repeated of it as a living animal, and which even though we discount the exaggerations and the misrepresentations respecting qualities which the animal does not and cannot possess, but still is not entirely divested of interest,—passing over these in a great measure, we shall first give some account of the appearance and characters of the living elephant, without any distinctions as to species, and then very briefly point out how the Asiatic and the African differ from each other, and how the northern or fossil elephant differs from both.

Generally speaking, the skin of the elephant is of a dusky black, with only a few hairs scattered over the general surface; but on the top of the head the hairs are much closer, and about the same length as hogs' bristles, to which indeed they bear no inconsiderable resemblance. A very imperfect notion of the appearance and texture of the skin of the elephant is obtained from examining the specimens which are shut up in menageries in this country, even in those places where they are treated with the greatest kindness and care. Their skin is invariably callous, and often apparently chapped or cracked into pieces, which have little or no sensibility. But when the animal is in good health and in its proper climate, and at its freedom, the skin is smooth and soft, and is probably almost as sensitive to the bite, even of a small insect, as the thinnest skin that can be imagined. When the animal is in this condition, there is indeed a wonderful power in the muscles of the skin, so that by the agitation of that alone an elephant is often capable of shaking off a wild beast. There is another difference of appearance between the elephant of the European shores and the elephant in its native forests, which it is necessary to attend to for the purpose of not being misled. The confined elephant has the skin loose and wrinkled, and apparently too big for it, whereas in a state of nature the skin is comparatively tight, and there is considerable plumpness in the appearance of the animal. It is probable that this difference, by means of which the confined elephant shows to so little advantage, is owing to the action of the colder climate on the skin; and this is another proof that the skin of the elephant possesses a good deal of sensibility when the animal is in proper health. This is indeed the case with the greater number of the *Pachydermata*, which really have the skin more sensitive than many of the thin-skinned animals; and thus, in so far as they are concerned, the usual associating of the epithet "thick-skinned" with the fact of want of feeling is incorrect.

The head of the elephant appears rather small in proportion to the size of the animal, but the form of the outline (in the Asiatic elephant particularly, which has the front-line nearly straight,) gives it an expression of intelligence. The eye adds considerably to this expression; for though very small in proportion to the size of the animal, it is bright and expressive. The ears are large and pendulous, though smaller in the Asiatic than in the African. The body is thick in proportion to its length and considerably arched in the line of the back, which gives the animal great strength in carrying. The legs are also very stout and massy. The feet are not divided into toes externally visible; but there are five short flat nails on each of the fore-feet, and four on each of the hind

ones. The feet and legs, though apparently stiff and awkward, are not so in reality. The fore-foot can be used with considerable adroitness as a sort of hand, in conjunction with the trunk, and both feet are used in stamping the enemies of the animal to death. The tail is slender and nearly naked for the greater part of its length; but it has a thick brush at the point, which, in the healthy animal, reaches nearly to the ground.

In size, elephants differ considerably; but when full grown they are rarely less than seven feet in height at the shoulders, or more than twelve. When they are below seven feet they are not considered fit for hard service, and none are purchased for the use of the British army in India, which do not stand this measure. The females, which are the most docile, are very seldom above eight feet; but the males are often considerably more. The following are the dimensions of a male measured in India, which was considered to have attained its utmost growth: from the line of the forehead to the insertion of the tail, fifteen feet eleven inches; perpendicular height at the shoulder, ten feet and a half; measure across the shoulders from the ground on the one side to the same on the other, twenty-two feet two inches and a half; and height of the crown of the head from the ground, set up as it is when the animal marches in state, twelve feet two inches. As the proportions of these measures to each other may be considered as pretty constant in adult elephants of all sizes, they will serve to give a general notion of the form of the animal.

The most singular organ in the elephant, and the one which most distinguishes it from all other living animals, is the proboscis or trunk, which, though one would not be apt to believe so from seeing it in a state of repose, is probably, the human hand only excepted, the most curious mechanical instrument in the whole animal kingdom. This proboscis is an extension of the snout of the animal, of a tapering or subconical form, and sometimes as much as eight feet in length. The two perforations in it, which answer the purpose of nostrils, can draw in water, or spout it to a considerable distance; and as the elephant cannot drink directly with the mouth, unless when immersed in water as far as the opening, the trunk answers the purpose of a drinking horn, as the animal can suck it full, and then, elevating the head and the basal part, and recurving the extremity downwards and inwards, blow the whole contents into the mouth. The extremity of the proboscis is on the upper side formed into a sort of rounded lip, which bears some analogy to the fingers of a hand, while the underside terminates in a single elongated tubercle, which has the same analogy to a thumb. The body of the trunk is made up of an immense number of muscles with their tendons, amounting in all to not less than four thousand, which is considerably greater than the number in the whole human body. Those muscles have their insertions in the external and internal coverings of the trunk; and they lie in a great variety of directions, some longitudinal, some nearly circular, and some oblique. The variety of motions which may result from the union of so many moving forces, so differently placed with regard to each other, and of which we may suppose, any number, from one to the whole, capable of moving at one time, is far greater than any ordinary arithmetic can sum up. The most powerful motion of the trunk is

that of the under side ; and when it curls round, which it sometimes does so as to form two hands, one by the curling fold, and one by the lip and tubercle at the end, the curl is always downwards, though it can complete a ring of the curl someway up the trunk, and leave a portion of the extremity free, by which means the prehensile part at the extremity can act upon what is held in the fold. The oblique muscles enable the trunk to be twisted, so as to place the loop of the fold longitudinally ; and with the trunk placed this way an elephant will hold a bottle and extract a cork with the greatest neatness. The oblique muscles also act in elongating and shortening the trunk, in a manner similar to that in which many of the *Annelidae*, or ringed animals can elongate and shorten their whole bodies. The trunk itself, from the great number of its muscles, is a very powerful instrument, and by means of it the animal can tear down a strong branch of a tree, lift a considerable weight, or hit a very severe blow. Upon examining the head of an elephant either in front or in profile, it will be seen that the insertion of the trunk is peculiarly strong. The bones of the lower part of the face are massy and strongly arched ; the neck is nearly of the same thickness as the head, and the muscles by which it is connected to the body are very powerful. The elephant does not butt with this powerful part of the head, as is done by various ruminating animals : but it can push along a very heavy weight, or break through a strong paling, by the dead pressure of its snout. Where tame elephants are used, this property is often turned to considerable account ; and those elephants which are in the service of the Indian merchants, may often be seen doing the work of a dozen of porters, in pushing about bales and boxes, and rolling heavy casks. In the wild state the trunk answers many important services. With it he gathers his food and puts it into his mouth, draws up water to quench his thirst, or to sprinkle his body, and collects dust, which he throws over his skin to disperse the mosquitoes and flies that annoy him. On all occasions he is most careful of his trunk, and unless when tied and picketed, he seldom uses it as a means of offence. The males use their tusks for this purpose, and the females endeavour, by falling upon the tiger, to crush him by their weight. The fact is that though elephants are exceedingly peaceable animals in their native haunts, unless when they are annoyed, or in the rutting season of the males, at which time they are in a state of excitement bordering upon fury, and are formidable to tigers and all other beasts of prey, and even to the rhinoceros himself, which, though perhaps a stronger animal in proportion to his size than the elephant, is not so susceptible of violent passions or so active in his motions.

Next to the trunk the most remarkable external character of the elephant is the tusks. These occupy the place of the ordinary canine teeth of animals, or rather perhaps that of the two great incisive teeth in the upper jaw, which belong to several of the rodent or gnawing animals, and to some of which the real teeth of the elephant bear a considerable resemblance, at least in the substances of which they are composed. The teeth, or rather tusks of the elephant, are not inserted by simple roots into the jaw or nasal bones, they are for a considerable part of their length toward the root hollow, and inserted on a conical core which perhaps gives them a firmer rooting than if they were placed in sockets. These teeth form the well known

substance, the ivory of commerce, and they often attain a very large size in the old males, the quantity of ivory in a single pair being sometimes at least one hundred and fifty pounds weight.

In the living elephants of both varieties, the tusks are either nearly straight, or curved upwards, or if their direction be nearly that of the line of the face they are inclined forward at the points. In the fossil elephant, on the other hand (at least in all the specimens which have been found), the curvature of the tusks is the other way, or downwards. What may be the use of this difference of structure it is not easy to say, because we know nothing of the habits of the extinct elephant, and very little of what the state of the country may have been when it was alive ; but, as the tusks in it are so constructed as that they might act as hooks in pulling down substances higher than itself, and as it is probable that the northern marshes were at that time covered with tree ferns, and those other palm-like plants, of which the remains are abundant in the fossil state, though not a vestige of the same plants now appears on the surface of the same regions, we may, perhaps, venture to conclude, that those tusks had been employed in pulling down the fronds of those plants, in order that the animals might feed upon them.

The tusks of the elephant are two in number, and they vary much with the age and sex of the individual, and there appear to be also permanent varieties of this kind, the cause of which is not known. In the females they are generally much smaller than in the males ; and it is not till the female has attained the age of several years, that they project beyond the mouth. In India, where elephants are most used, and therefore more attended to than any other part of the world, there are several distinctions made from the size and shape of those extremities. The perfect elephant, called *pulley dant*, has the tusks projecting forwards and upwards. Those called *daunteleh*, or elephants with large teeth, vary from the projecting horizontal, to the nearly straight tusks of the mooknah, which point directly downwards. Between these two there is a great variety in the form of the tusks. The largest teeth found in the male elephant, are from five to eight feet in length, and from four to eight inches in diameter, and weigh from twenty to eighty pounds each tooth. In the mode of their growth, though not in their substance, their tusks bear a much nearer resemblance to the hollow horns of the ruminantia ; and, indeed, from the vast quantity of animal matter, and the comparatively small portion of salts of lime, ivory approaches, perhaps, as near to horn as it does to bone, and more so than to enamel, of which the tusks of the elephant contain little or none. In their very young state, elephants have milk tusks, which have very little adherence to the bones of the head : those drop off when the animal is about fourteen or fifteen months old, and soon after the permanent tusks make their appearance, and are not shed while the animal lives. They continue growing by a new layer of ivory on the inner surface, which is secreted by the pulpy substance on the core filling the hollow, just as is the case with the horn of an ox ; and as each of these new layers is a complete cone of ivory, extending to the very point of the core, the solid part of the tusk increases in length, in proportion to the general growth of the whole.

There are no cutting teeth in the lower jaw of the

elephant, or indeed any other teeth answering to the tusks of the upper jaw. The rest of the teeth have their crowns, generally speaking flat, but from the way in which they are constructed, they are well adapted for cutting and bruising those hard substances upon which elephants are at times obliged to feed. Those teeth which are the only useful ones to the animals, in preparing their food for the stomach, may be compared to a set of irregular chisels placed across the jaw, and supported in the intervals by a substance much softer, and bearing some resemblance to the ivory of the tusks, though probably not so hard, and containing more animal matter. The protuberant ridges, which we have said resemble irregular chisels, are formed of the hardened enamel; and though, from the quantity of food which so large an animal requires, they are subject to wear, they are always higher than the intervening substance by which they are supported; and it is probable, also, that this substance, being in so far elastic, gives way a little when the food requires a powerful bite.

In the Asiatic elephant, which is the only one of which the progress has been accurately observed, the first grinders, or milk-teeth as they are called, begin to cut the surface as early as nine or ten days after the birth. Those grinders consist of four laminae, or ridges of enamel; but they are altogether of soft texture, so that they soon wear away. They are not shed, as is the case with the milk-teeth of some other mammalia, and with the milk-tusks of the elephant itself; but are worn away gradually while the second set are coming forward; and by the time that these are full grown, which is the end of about the second year, the body of the first ones is completely worn away, the roots are absorbed, and every vestige of the teeth is obliterated. The second teeth contain eight or nine laminae, or about double the number in the first, and the jaws lengthen proportionately to give them room. When the second set are perfected, and have to perform the whole labour of mastication, by which they are to be in time worn away, the third immediately begin to form in the rear of them; and they continue growing from the end of the second to the end of the fifth year, by which time the second teeth are nearly exhausted, and the third occupy their place. These third ones have twelve or thirteen laminae, and are consequently much longer, that is, they occupy a greater length of the jaw than their predecessors; and the jaw itself of course lengthens in proportion. The third set lasts from the beginning of the sixth year to the end of the ninth, at the last of which periods it gives place to the fourth set, on which the number of laminae to each tooth is fifteen or sixteen. This process goes on during the life of the animal, every succeeding set of teeth consisting of a greater number of laminae, occupying a greater length of the jaw, and requiring at least a year longer than its predecessor to bring it to maturity.

We have been thus particular in describing the mode of dentition in the elephant, because there is nothing like it in the whole animal kingdom; and as it evinces a power of reproduction without end in the teeth which those animals use in feeding, it may be considered as an indication of great longevity; the more so, that the teeth of most animals are the parts of them which are apt to suffer the earliest decay. There is something slightly analogous to this in the cutting teeth of some of the rodent animals, especially in those which have to gnaw bark and other hard

substances for their food; and these are the teeth which in their substance most resemble the teeth of the elephant. Those teeth in the rodent animals are, however, simply cutting teeth, and not used in bruising or grinding their food; they are therefore simple chisels, with a layer of enamel on the front side, and the supporting substance, which is not unlike ivory, placed behind, and so much lower on the gum as to allow the cutting edge of the enamel to act. Those teeth grow for life, as well as the teeth of the elephant; but they do this, not by any replacement of the old tooth by a new one, but by the growth of the same individual teeth at the roots, as they are worn away at the points. Thus the analogy between them is comparatively a very slight one; and the elephant must still be allowed to be the only possessor of that singular reproduction of the teeth, by which it is distinguished from every other known animal.

But though this reproduction of the teeth is, in itself, a very decided proof that elephants are long-lived animals, it furnishes us with no data whereby we are able to ascertain the exact age to which they live. Nor have we sufficient knowledge of elephants in a state of nature for enabling us to get at the fact by observation, as elephants in this state are not often seen, except when they are to be captured for servitude, or hunted for the sake of their tusks, the last of which, probably, conduces the most to their extermination. There are recorded instances, however, of elephants living to the age of one hundred and fifty years in a state of servitude; and if we add half to that period, or even double it, we shall not perhaps over-rate their duration in a state of freedom.

It is probable that the decay of elephants in old age arises from the stiffening of the joints; for four or five tons constantly borne, is a heavy pressure on the working structure of an animal. This stiffening of the joints in advanced age may also, in part, have given rise to the old fabulous belief, that elephants are incapable of bending their legs, so as to lie down, or even to kneel, for the purpose of repose. In the case of young elephants this is not true, for they lie down to sleep in the same way as other animals, though probably not quite so often. When they are old they are said not to lie down often, even for the purpose of sleeping; and instances are mentioned of elephants in India, subjected to labour, which did not lie down for twelve months or more, though, they occasionally slept a little on their feet. The wild ones are said to take their occasional repose leaning against the bole of a tree. In confinement in this country, we believe, they take their repose leaning against the sides of their dens; but an elephant in a den, and exposed to the climate of this country, is so much out of its natural element, that no conclusion drawn from observing it will apply to the race in a state of nature.

The voice of the elephant, as usually heard in a state of confinement, is almost as hollow as the roar of a lion, though it wants the peculiarly offensive roughness of the lion's voice, which grates so harshly upon the ear, and puts one in mind of the rending and mangling of the flesh of animals. But this disagreeably hollow sound is not the only one uttered by the elephant, or even the most common one, where the animal is free and at its ease. The elephant has three voices: one which is shrill, but ends in a murmur, as if the animal were coaxing; one which is deep, but soft and complaining; and one,

# ELEPHANTS.

African Elephants. Male & Female.

Indian Elephant.

which is the harsh and hollow roar, which is most frequently heard from the confined animal. The first of these is sportive, and, so long as the animal utters it, there is nothing to be feared. The second is complaint, and, if the cause of it be found out and removed, it will give place to the first, and there is still no danger; but the third is indignation or revenge, or both united, and then it is not safe to come near the animal.

From the character of their teeth, the only teeth which they use in the preparation of their food, it is needless to say that elephants feed only upon vegetable substances. As is very generally the case with vegetable feeders, they prefer succulent matters, and especially such as are sweet, or have otherwise an agreeable flavour. In their native forests it is possible that they do not meet with much food of this kind, but subsist chiefly upon the coarse grasses in the openings of the forests, and the leaves and young branches of shrubs and trees. They are social and gregarious animals; and the herds in which they assemble depend, of course, upon the extent and richness of their forest. The old and young ones associate together without the slightest animosity; and though it is not ascertained that the numbers of the two sexes are equal, or that they live in pairs, yet they are almost invariably led on by the eldest male and the eldest female, which move in advance, and the others appear implicitly to follow their motions. In India elephants are most abundant in the thick woods on the left bank of the Ganges, along the Brahmapootra, and in the forests of Chittagong, farther to the east. The places of Bengal, in the immediate neighbourhood of the forests on the Ganges, are exceedingly rich, and well adapted for all the more valuable products of the Indian soil; and, therefore, in them cultivation is carried closer to the forests than in the less fertile parts of the country. The consequence is, that elephants, though perhaps not so numerous there as in Chittagong, are much more frequently seen. The herds also occasionally invade the cultivated fields, eating vast quantities of green sugar-canes, rice, bananas, and other crops, and trampling down and destroying the remainder with their great feet. They are also very bold and very formidable in their invasions; and unless the people can rise *en masse*, and drive them off with torches and cannon shot, they must just look on, and behold the ruin of their fields, until it shall please the elephants to retire.

The keeping of an elephant is a very expensive matter, the quantity of food required being from one hundred to one hundred and fifty pounds' weight every day. This is, however, the quantity estimated for a full-grown elephant in perfect health; and the small and sickly ones, which are generally in this country, do not require so much food. Chunees, whose death, or perhaps murder, in the menagerie at Exeter Change, some years ago, excited so much of the public attention, was a sturdy fellow in this way; and though he had been cooped up in menageries, and been made to play on the boards of national theatres, kept his health well, and grew apace till he reached the weight of nearly four tons. No inquest was held upon him, but it was whispered among zoologists that Chunees's fury was not the sole cause of his death. The two supplemental ones which were mentioned were, first, that as the place was to be taken down and the animals removed, the removal of Chunees would have

been a matter of great expense and labour, and not altogether free from danger, either to himself or to those about him; and, secondly, that Chunees required so much food, and people had become so familiarised to the sight of him, that he had become a losing speculation. We know not what truth there may be in these surmises, or whether there may be any truth in them at all, though we mention them as connected with one of the largest and most vigorous elephants that ever was exhibited in this country. True or false, no blame whatever can by possibility attach to the owner. The animal was property lawfully purchased; and we know of no law to prevent a man from killing his own elephant, any more than for killing his own mutton.

As we hinted in a previous part of this article, the old prejudice that elephants scorn to breed in a state of confinement, is totally without foundation. From the great excitement of the males during the rutting time, it is natural to suppose that when they are in confinement, or poorly fed, or severely worked, their system will not be stimulated to the requisite degree; and, therefore, the young elephants which are born in confinement are exceedingly few; and no instance of it has occurred in modern Europe. From some accounts given both by Ælian and Columella, it should seem that in the time of the Romans, when elephants were kept by them for the purposes of ostentation or of war, there were at least a few of young produced in confinement. But the most decisive evidence that we have of this point is from Mr. Corse Scott, who from his residence at Tipperah, in the eastern part of Bengal, had excellent opportunities of studying the natural history of elephants, and who improved those opportunities to admiration. Mr. Scott had an elephant born on his own premises, both parents of which were in his possession for some time previous to the commencement of the gestation. By this means Mr. Scott established, for the first time, we believe, an important fact in the economy of these animals, namely, the exact length of time that the female goes with young. This had been previously mentioned by writers on the natural history of the elephant, but apparently from hearsay; but Mr. Scott ascertained it to be from the first of July, 1793, to within a day or two of the first of April, 1795, which may be considered as exactly twenty months; and from all the rest of his observations he had no reason to conclude that the period is ever different from this. Both of Mr. Scott's elephants were above the standard required by the army in India; but the female was not old, for during the period of her gestation she increased five inches in height.

The young elephant at its birth stands about three feet high, and it grows nearly a foot more the first year, two-thirds of a foot the second, half a foot the third, five inches the fourth, rather less in the fifth, between three and four inches in the sixth, and two and a half in the seventh. Thus, there is a yearly diminution in the quantity grown; and it is probable that ultimately this growth ceases, though there is every reason to believe that the oldest elephants of both sexes are the largest.

The young begins very early to suck; and while it performs this operation with the mouth, it at the same time presses the teat with the trunk to aid the flow of the milk. In a state of nature, the female elephant appears to have very little attachment to her young, less so than most animals; for it is stated that when a female

with her young one is captured, two or three days' absence will make her entirely forget it—though the young one itself recognises her, and utters the most plaintive cries for the purpose of attracting her attention. This fact, which appears to be well authenticated, is pretty strong evidence against the sagacity, affection, and other half-reasoning qualities which fiction has attributed to the elephant.

As the pastures of the elephant are perennial pastures which feel no season of want—and, indeed, such pastures only are adapted to animals requiring so much food, elephants have no rutting season, common or nearly common to the whole herd, for young ones are found at all stages of their growth at almost every season of the year. The length of time during which the female elephant suckles her young one, has not been accurately ascertained; and, indeed, from the indifference to it which we have mentioned that she shows, it is highly probable that the period varies much according to circumstances. There seems to be a natural provision for this in the early appearance of the milk teeth in young elephants, which, though small in the first instance, appear to be capable of masticating the softer vegetables when the animal is only a few weeks old: this may be a necessary provision in the economy of elephants, because at certain seasons the female may have to range farther and faster for food than her young one is able to follow her, while the place which she leaves may still afford a supply sufficient for the support of her deserted offspring.

Notwithstanding the great size and strength of the elephant, the fury which he evinces when excited, and the perfect safety in which he lives in forests which contain the most bold and ferocious beasts of prey, and the most formidable reptiles, he is no match for man, in even the lowest degree of civilisation. The rude man has only to kindle a fire, and the elephant flies in the utmost consternation; or he digs a pit, and conceals it with green boughs; the elephant falls into it, and his very weight and strength are the means of his destruction. The elephant is to all appearance safe from the paw of the tiger, the jaws of the alligator, the crushing folds of the python, and the poison of the most deadly serpent; but he has no defence against the wiles of man. The countries which he inhabits contain, amid the luxuriance with which they are adorned, vegetable poisons of the most mortal character. The rude man has found out by experience how to concentrate these, till they shall speedily curdle the blood, or enumb the frame even of the elephant. So he dips his weapon in the deadly virus, bends his simple bow, sets his arrow on the string, takes his aim with certainty, and in brief space the giant volume of the elephant tumbles lifeless on the earth.

The animal senses of the elephant appear to be all very acute; while he is in health the whole of the skin is sensitive to very trifling causes; and the top of the proboscis has probably as keen a sense as the points of the human fingers. His eye, also, is keen, though the range of his vision is probably not very extensive. Indeed, sight is not the most useful sense in such places as those which the elephant inhabits; and the senses of animals are in general adapted to the nature of their haunts. The sense of hearing is a much more serviceable one, among tall vegetation, than that of sight; and from the size of the elephant's ears, and the freedom with which he can move them

backwards and forwards, there is reason to conclude that, in him, this sense is very acute. That the sense of taste is far more keen than in many animals that feed upon vegetables, is proved by the fact of the elephant being so partial to sweet or racy vegetables, and even to sweetmeats. The sense of smell appears, however, to be the leading one, both in enabling the elephant to find that which he seeks, and to avoid that which it is his instinct to shun. Some naturalists have said that the proboscis does not possess this sense, but the saying appears to be a mistake. Every animal which has a perforated nose, whether that nose be long or short, uses it as an organ of smelling; and no good cause can be shown why the elephant should be an exception to the general rule. From the other functions which this organ performs, it must be very copiously supplied with nerves; and we have direct evidence that the elephant chooses or rejects those articles which are offered to him by means of his proboscis; nor is there any instance mentioned of his having ever attempted to distinguish scent by means of any other part of his body. But the elephant hunters know full well how necessary it is to give the elephant the wind, or approach him on the lee-side only; for if they attempt to come upon him from the windward, he is either off, or so excited and prepared, that he becomes the hunter, and they the hunted.

The intelligence usually attributed to the elephant is a different matter. We cannot say positively that the intelligence of any animal is in the ratio of the volume of its brain as compared with that of the whole body, because the functions of the brain are of too obscure and delicate a nature for being made the foundation of absolute demonstration. Still the degree of animal sagacity, leaving intellect altogether out of the question, bears some relation to the volume of the brain, although we are not able to say that they follow the same numerical proportion, or even to state the law in a numerical series of any kind.

That there should be an increase of the one with an increase of the other, is in perfect accordance with the general analogy of nature, which runs through the whole system of animal life, and forms no small part of the beauty of that system. The power, especially the mechanical power, of a particular organ, such as the clutching of a paw or the turning of a proboscis, is a local matter, and may depend on the extent to which that particular organ is furnished with the energy of life; and ganglions and local nerves may accomplish this in the largest of the mammalia, as well as in the most minute of the insect tribe. But that which we call sagacity does not depend on any thing local, it belongs to the whole system; and, therefore, if we are to refer it anywhere, we might refer it to the brain, or the central mass of the nervous system; at least, if we do not this, we must abandon all analogy, and set at nought the results of all observation; well, if we compare the brain in man with the whole mass of the body (and the human brain can be no more mental, at the same time that it is more material, than the brain of any other animals); and if we make the same comparison in the elephant, we find that in man, when not overloaded with fat (which is not understood to be particularly favourable to sagacity), the volume of the brain is to that of the whole body in the ratio of about 1 to 212. But if we make the same practical comparison in the elephant, we find the brain to the body in the ratio of only about 1 to 500, thus forming a very small

part of what it proportionally is in man. In as far as the analogy of nature is concerned, what has been now stated appears to be conclusive against any high degree of sagacity in the elephant, even as compared with other animals. It is certainly inferior to the dog, and probably also to the pig, an animal which we are not in the habit of rating very high in the scale of intelligence. But the pig may be taught as many tricks as the elephant, though it wants some of the mechanical apparatus for the performance of them; and a pig has been trained to stand and point at game, which no elephant ever did, even under the immediate guidance of its mahaut, with the conducting iron stuck in the top of its head.

Whence, then, could have arisen the very general belief in the sagacity of the elephant; and why have the Hindûs given it a place in their temples as the god, or, at all events, the emblem, of wisdom? The second of these questions, probably, involves in it the answer to the first. The Hindûs are not very particular in the choice of their gods; and a people who can believe that there is certain salvation in the possession, or the mere vicinity, of a fossil shell (the *Salgram stone*, which is simply a *Cornu Ammonis*), or that cow dung is the most sacred of all substances, cannot be expected to be very skilful or accurate in their choice of the god or any emblem of wisdom. Among the ignorant, what is considered as a wise look (though proverbially a sign of folly among the better informed) is generally held to be the certain indication of absolute wisdom. An owl is among the most stupid of birds, which, taken altogether, are a stupid race as compared with the mammalia; and yet the owl was the symbol of wisdom among the most polished, and, on some points, the most philosophical people of ancient times. We have not made these few remarks with any view to the disparagement of the elephant, but only to correct the vulgar prejudice respecting it, and to elevate it to its true and proper place in the animal kingdom, by doing what we can to reduce the accounts of them within the bounds of sober truth and real usefulness.

When noticing the principal haunts of elephants in the wild state, we omitted to mention, that though they are found in places which have always too much moisture to prevent their being burnt up, and are seldom far from the water, and very often swimming and bathing in it with apparent pleasure; yet they always prefer the clear waters, which have their banks comparatively firm. They sometimes spout muddy water over their bodies with their trunks; but they do not wallow in the mud, or walk upon the surfaces of deep and sludgy quagmires. Their weight and the form of their feet are both ill adapted for such places, and they would sink into them beyond the power of extrication. Neither are their feet suited to rough and stony paths, nor even to those which are very much indurated, as the soles of them are apt to get bruised, and thus the feet of an elephant are the first parts that fail on a long march. Elephants also move but slowly up a hill, evidently on account of their great weight, and although the same weight accelerates their motion down hill, they are very much shaken and jaded by resisting the downward impulse. Their place of best, or at all events of longest continued motion, is upon level ground.

Such is a summary of the greater part of what is known of the elephant, in a state of nature; and it

relates wholly, or chiefly, to the Asiatic species, for the African one is hardly known, except as a hunted animal, for his tusks, his flesh, or both—an elephant being a feast of many days to the inhabitants of an African village.

But from the length of time that the elephant has been pressed into the service of man, for purposes of ostentation, or for labour, makes him interesting as connected with human history. Our notice of him in this way must be very brief, but it would be incomplete if we did not prepare it by a short account of the manner in which elephants are captured. This we shall take in substance, but in a very abridged form, from the account given by Mr. Corse Scott, and first published in the Asiatic Researches. We shall do this because it is the production of a man of practice, as well as intelligence, drawn up from his own experience as a regular elephant catcher, at a time when these animals were in much demand in India.

We may observe, that the country from the Ganges and Brahmapootra eastward to the Mug mountains, and from Chittagong, on the bay of Bengal, northward to the mountains of Assam, is remarkable for the humidity of its climate, and the luxuriance of its vegetation, both in forest trees and in shrubs and herbaceous plants. It lies in the line of both monsoons: and thus its dry season is very short, as compared with that of India generally. Some of the lower parts are swampy and unhealthy; but a considerable extent consists of gentle slopes of firm ground, covered by rich forests and under growth, and in every respect a chosen country for elephants.

In this country the herd of elephants is taken wholesale, by being driven into a series of inclosures called *keddah*. This in general consists of three inclosures, formed of very strong stockades on the outside of deep ditches; the third, or innermost inclosure, being usually the strongest of the three. It requires to be elephant proof, because, when the animals get as far as it, they are generally in a state of great excitement.

Previous to the hunt, some of the most intelligent of the natives, who are conversant with the woods, and experienced in discovering the elephants without alarming them, are sent out to find the herd, and to note particularly the direction in which it is ranging; for as elephants clear the pasture before them, almost as completely as reapers, they range on a course for the distance of many miles. When they are discovered, the *keddah* is constructed at a considerable distance in front of them, but in the line of their advance; and all things being thus ready they proceed to the capture, which is a matter requiring great skill and attention, and by no means unattended with danger. When a herd is discovered, about three hundred people are employed to surround it, who divide themselves into small parties, consisting generally of three men, each at the distance of about twenty or thirty yards from the other, and form an irregular circle, in which the elephants are inclosed; each party lights a fire, and clears a foot-path to the station that is next him, by which a regular communication is soon formed through the whole circumference from one to the other. By this path reinforcements can immediately be brought to any place where an alarm is given: and it is also necessary for the superintendents, who are always going round, to see that the people are alert upon their posts. The

first circle being thus formed, the remaining part of the day and night is spent in keeping watch by turns, or in cooking for themselves and companions. Early next morning, one man is detached from each station, to form another circle in that direction, where they wish the elephants to advance. When it is finished, the people stationed nearest to the new circle put out their fires, and file off to the right and left, to form the advanced party, thus leaving an opening for the herd to advance through, and, by this movement, both the old and new circle are joined, and form an oblong. The people from behind now begin shouting and making a noise with their rattles, drums, &c., to cause the elephants to advance; and as soon as they are got within the new circle the people close up, take their proper stations, and pass the remaining part of the day and night as before. In the morning the same process is repeated, and in this manner the herd advances slowly in that direction, where they find themselves least incommoded by the noise and clamour of the hunters, feeding as they go along upon branches of trees, &c. If they suspected any snare, they could easily break through the circle; but this inoffensive animal, going merely in quest of food, and not seeing any of the people who surround him, and who are concealed by the thick jungle, advances without suspicion, and appears only to avoid being pestered with their noise. As fire is the thing elephants seem most afraid of in their wild state, and will seldom venture near it, the hunters always have a number of fires lighted, and particularly at night, to prevent the elephants coming too near, as well as to cook their victuals, and keep them warm. The sentinels supply these fires with fuel, especially green bamboos, which are generally at hand, and which by the crackling and loud report they make, together with the noise of the watchmen, deter the elephants from coming near; so that the herd generally remains at a distance near the centre of the circle. Should they at any time advance, the alarm is given, and all the people immediately make a noise and use their rattles, to make them keep at a greater distance. In this manner they are gradually brought to the keddah. As soon as they all have entered the gateway, fires are lighted round the greater part of the inclosure, and particularly at the entries, to prevent the elephants from returning. The hunters from without then make a terrible noise, by shouting, beating of drums, firing blank cartridges, &c., to urge the herd on to the next inclosure. The elephants, finding themselves ensnared, scream and make a noise, but seeing no opening except the entrance to the next enclosure, and which they at first generally avoid, they return to the place through which they lately passed, thinking, perhaps, to escape, but now find it strongly barricaded; and as there is no ditch at this place, the hunters, to prevent their coming near, keep a line of fire constantly burning all along where the ditch is interrupted, and supply it with fuel from the top of the palisade; and the people from without make a noise, shouting and hallooing to drive them away. Wherever they turn they find themselves opposed by burning fires, or bundles of reeds and dried grass, which are thrust through the opening of the palisades, except towards the entrance of the second inclosure. After traversing the first inclosure, and finding no chance of escaping but through the gateway into the next inclosure, the leader enters, and the rest follow; the gate is instantly

shut by people who are stationed on a small scaffold immediately above it, and strongly barricaded, fires are lighted, and the same discordant din made and continued till the herd has passed through another gateway into the last inclosure, the gate of which is secured in the same manner as the former was. The elephants being now completely surrounded on all sides, and perceiving no outlet through which they can escape, appear desperate, and in their fury advance frequently to the ditch, in order to break down the palisade, inflating their trunks, screaming louder and shriller than any trumpet, sometimes grumbling like the hollow murmur of distant thunder; but wherever they make an attack, they are opposed by lighted fires, and by the noise and triumphant shouts of the hunters. As they must remain some time in this inclosure, care is always taken to have part of the ditch filled with water, which is supplied by a small stream, either natural, or conducted through an artificial channel from some neighbouring reservoir. The elephants have recourse to this water to quench their thirst after their fatigues, by sucking the water into their trunks, and then squirting it over every part of their bodies. While they remain in this inclosure they continue sulky, and seem to meditate their escape; but the hunters build huts around them close to the palisade, watchmen are placed, and every precaution used to prevent their breaking through.

When the herd has continued a few days in the keddah, the door of the outlet is opened, into which some one of the elephants is enticed to enter, by having food thrown first before, and then gradually further on into the passage, till the elephant has advanced far enough to admit of the gates being shut. Above this wicker gate two men are stationed on a small scaffold, who throw down the food. When the elephant has passed beyond the door, they give the signal to a man, who, from without, shuts it by pulling a string, and they secure it by throwing two bars that stood perpendicular on each side, and which cross each other in the form of the letter X, and then two similar bars are thrown across each other, behind the door next to the keddah, so that the door is in the centre. For further security, horizontal bars are pushed across the outlet, through the openings of the palisades, both before and behind those crosses, to prevent the possibility of the door being broken. The outlet is so narrow that a large elephant cannot turn in it, but, as soon as he hears the noise that is made in shutting the gate, he retreats backwards, and endeavours to force it; being now secured in the manner already noticed, his efforts are unavailing. Finding his retreat thus cut off, he advances and exerts his utmost force to break down the bars which were previously put across, a little farther on in the outlet, by running against them, screaming and roaring, and battering them like a ram by repeated blows of his head, retreating and advancing with the utmost fury. After he has fatigued himself in this confinement, strong ropes with running nooses are laid down, and as soon as he puts a foot within the noose, it is immediately drawn tight and fastened to the palisade. When all his feet have been made fast, two men place themselves behind some bars that run across the passage, to prevent his kicking them, and with great caution tie his hind legs together by passing a cord alternately from one to the other, like the figure  $\infty$ , and then fastening these turns in the middle. A strong rope is now put twice round his body, close to his fore legs, like a girth,

and tied behind his shoulders, then the long end is carried back close to his rump, and there fastened, after a couple of turns more have been made round his body. Another cord is next fastened to the girth, and from thence carried under his tail like a crupper, and brought forward and fastened by a turn or two to each of the girths by which the whole is connected, and each turn of the cords serves to keep the rest in their places. After this a strong rope is put round his back, and made fast on each side to the girth and crupper, so as to confine the motion of his thighs, and prevent his taking a full step. These smaller ropes being properly adjusted, a couple of large cables with running nooses are put round his neck, and, after being drawn moderately tight, and the nooses secured from running closer, they are tied to the ropes on each side. While these operations are going on, the other hunters stand before the gate of the passage, tickling his trunk, and diverting his attention with a spike or a bunch of cocoa-nut leaves, or sugar canes, so that the cords, in general, are made fast without much opposition or difficulty. Occasionally, however, he will seize hold of the ropes with his trunk and endeavour to break them, particularly those which are tied about his feet, or he will try to bite them through with his grinders, but the hunters then goad him with sharpened bamboos, or very light spears, so as to make him quit his hold. Those who are employed in putting the ropes round his body and over his head, are stationed above him on a small kind of platform, consisting of a few bars run across through the openings of the palisades, and as an elephant cannot see anything that is above and rather behind his head, they are very little incommoded by him, although he appears to smell them, and endeavours to catch them with his trunk. As soon as the whole of the apparatus is secured in a proper manner, the ends of the two cables which were fastened round his neck, are brought forward to the outer end of the outlet, where two tame elephants, which are trained to the business, are waiting, and to them these cables are made fast. After every thing is prepared and ready, the door at the end of the passage is opened, and the ropes that tied his legs to the palisades are unfastened.

If the elephant is not very formidable or unruly, it is sufficient to place him lengthwise betwixt two large trees, about thirty or forty feet distant from each other, there to bind his legs in contact together, and fasten them close to one of the trees with six or seven turns of thick rope; likewise to bind one fore leg, to which greater liberty is given by the length and slackness of the cordage. The two tame elephants are then disengaged from the wild one, and conducted back by the tail to take charge of another captive. This is a very trying moment to the wild elephant. While guided by the tuition, and soothed by the society, of his subjugated brethren, he remains tranquil and quiet, appearing to forget his sorrows, and to gather fortitude under his sufferings; but immediately that his companions march away, finding himself closely bound, a solitary and helpless prisoner, he is agitated with all the horrors of despair, breaks out into a roaring which makes all the forest tremble, and in the fury of his extravagant grief frequently falls a sacrifice to the exertion which he makes in trying to regain his liberty. During this period, cocoa-nut leaves and plantain trees are brought to him for food. In the agony of distress,

he tosses them contemptuously away, or tramples them with indignation under his feet. The cravings of hunger, however, will after a while induce him to eat, which he does with great reluctance at first, but becomes gradually more resigned, and after the lapse of a few hours he will feed very heartily. Whole herds of elephants are taken captive in this manner; but occasionally a small party of hunters endeavour to seize the males, which often sally forth from the forests alone in search of richer provisions. In this object the hunters are frequently successful, by observing the following plan:—The places where the elephants feed are known to the hunters, they advance towards them in the evening with four trained elephants. When the nights are dark these stragglers are discovered by the noise they make in cleaning their food, by whisking and striking it against their fore legs; and by moonlight people can see them distinctly at some distance. When they have determined upon the particular elephant they mean to secure, three of the trained females are conducted silently and slowly by their drivers, at a moderate distance from each other, near to the place where he is feeding. These advance very cautiously, feeding as they go along, and have the appearance of wild elephants that have strayed from the forest. When the male perceives them approaching, if he takes the alarm, and is viciously inclined, he beats the ground with his trunk, and makes a noise, showing evident marks of his displeasure, and that he will not allow them to approach near; and, if they persist, he will immediately attack and gore them with his tusks; for which reason they take care to retreat in good time. But should he be amorously disposed, which is generally the case, he allows the females to approach, and sometimes even advances to meet them. If from these appearances the hunters judge that he will become their prize, they conduct two of the females, one on each side, close to him, and make them advance backwards, and press gently with their posteriors against his neck and shoulders. The third female then comes up, and places herself directly across his tail. So far from thinking of any design, in this situation, against his liberty, he begins to toy with the females and caress them with his trunk. While thus engaged, the fourth female is brought near with ropes and proper assistants, who immediately get under the belly of the third female, and put a small cord round his hind legs. At this time, should he move, it is easily broken, and if he takes no notice of this slight confinement, nor appears suspicious of what is going forward, the hunters then proceed to tie his legs with a strong cord, which is passed alternately by means of a forked stick and a sort of hook, from the one leg to the other, as we have described before. A very strong cable with a running noose, sixty cubits long, is next put round each hind leg, immediately above the cords, and these are secured in their places by other cords tied round the legs above them. It generally takes about twenty or thirty minutes in putting on these ropes, during which the utmost silence is observed; and the hunters who keep flat upon the necks of the females, are covered with dark coloured clothes, which serve to keep them warm, and at the same time do not attract the notice of the elephant. While the people are thus employed in tying his legs, he sometimes caresses one and sometimes the other of his seducers, examining their beauties, and toying with them, by which his

desires are excited, and his attention diverted from the hunters, and in these amorous dalliances he is indulged by the females. He is now generally so firmly secured by the pressure of the tamed elephants on each side, and by the one behind, that he can hardly turn himself or see any of the people, who always kept snug under the belly of the third female that stands behind, and serves both to keep him steady, and to prevent his kicking any of the people who are employed in securing him; but in general he is so much taken up with his decoyers, as to attend very little to anything else. In case of accidents, however, should he break loose, the people upon the first alarm can always mount on the back of the tamed elephants by means of a rope that hangs ready for the purpose, and thus get out of his reach. When his hind legs are properly secured, they leave him to himself, and retire to a small distance; but, as soon as the females go away, he attempts to follow them, but, finding his legs tied, he is roused to a proper sense of his situation, and retreats towards the forest. The hunters now follow at a moderate distance on the females, accompanied by a number of people that had been previously sent for, and who, as soon as the wild elephant passes near a stout tree, make a few turns of the long cables that are trailing behind him, around its trunk. His progress being thus stopped, he becomes furious, and exerts his utmost force to disengage himself; nor will he then allow any of the females to come near him, but is outrageous for some time, falling down, and goring the earth with his tusks.

Should the cables once break by these exertions, which sometimes is effected, and he escapes into the forest, the hunters dare not advance for fear of the other wild elephants, and are therefore obliged to leave him to his fate; and, in this hampered situation, it is said he is even ungenerously attacked by the other wild elephants. As the cables are very strong and rarely give way, such accidents seldom occur. When he has by his exertions exhausted himself, the trained elephants are again brought near, and take their former positions. After getting him nearer the tree, the people carry the ends of the long cables round his legs, then back and about the trunk of the tree, making if they can two or three turns, so as to prevent even the slightest possibility of his escape. To confine him from moving to either side, and for farther security, his fore legs are tied exactly in the same manner as the hind legs were. With all the expedition possible, he is now harnessed in the same manner as those already described, and conducted to his proper station. As soon as each of the elephants is thus secured, he is left in charge to a keeper, who is appointed to attend and instruct him, and four or five inferior servants, in order to assist and supply food and water, till he becomes so tractable as to bring the former himself.

The first object of the keeper is to gain his confidence, and, for this purpose, he constantly supplies him with food, and soothes and caresses him by a variety of little arts. Sometimes, however, the keeper threatens, and even goads him with a long stick pointed with iron, but more generally coaxes and flatters him, scratching his head and trunk with a long bamboo, split at one end into several pieces, and driving away the flies from any sores occasioned by the hurts and bruises he got by his efforts to escape. The keeper likewise keeps him cool by squirting

water over his body. In a few days he advances cautiously to his side, and pats and strokes him with his hand, speaking all the while to him, in a soothing tone of voice, and in a little time he begins to know his keeper, and to obey his commands.

The keeper at length by degrees becomes familiar to him, gets upon his back from one of the tame elephants, and as the animal becomes more tractable, he advances gradually forward, till at last he is permitted to seat himself on his neck, from which place he afterwards regulates all his motions. The iron hook with which they direct him is pretty heavy, about sixteen inches long, with a straight spike advancing a little beyond the curve of the hook. When he wishes to turn him, he catches one of his ears with this instrument, and by pressing it into his skin makes him move in any direction that is required. While he is training in this manner, the tame elephants lead out the others in turn for the sake of exercise, and likewise to ease their legs from the cords with which they are tied, and which are apt to gall them severely, unless they are regularly slackened and shifted. In the course of five or six weeks, the elephant becomes obedient to his keeper, his fetters are taken off by degrees, and generally in about five or six months he suffers himself to be conducted by his keeper from one place to another. Care, however, is always taken not to let him approach his former haunts, lest a recollection of the freedom he enjoyed there should induce him to recover his liberty again. This obedience to his conductor seems to proceed partly from a sense of gratitude, as it is in some measure voluntary; for whenever an elephant takes fright, or is determined to run away, all the exertions of the keeper cannot prevent him, even by beating or digging the pointed iron hook into his head with which he directs him. On such an occasion, the animal totally disregards the feeble efforts, otherwise he could shake or pull him off with his trunk, and dash him to pieces. Accidents of this kind happen almost every year, especially to those keepers who attend the large males, and are in general owing to their own carelessness and neglect.

The males are treated with much greater severity than the females which is necessary to keep them in awe; but it is too common a practice among the keepers either to be negligent in using proper means to render their elephants tractable, or to trust too much to their good nature, before they are acquainted with their dispositions thoroughly.

It will readily be understood that, in order to repay all the labour and compensate all the risk with which their capture is attended, elephants, when taken and trained to docility, must be of great value; and perhaps we cannot give a more correct estimate, whereby the value of an elephant may be compared with that of other animals employed in draft or carriage, than by stating that a male elephant full grown, of the largest size, and in the best health and condition, can carry about a ton weight, and travel with it fifty miles in the course of twenty-four hours; and that, if properly used, he may perhaps retain this power for a century or even more; so that he who purchases a good elephant may be said to purchase an estate for his grandchild. Carrying is not the only useful purpose to which those powerful animals can be applied; for their weight and strength tell equally in traction; and in this respect their strength tells much more in proportion to the strength of horses or bul-

locks than it does in carrying. In using a team of horses, the proportional expense increases, and that at a pretty rapid rate; in proportion to the number used. The reason of this is obvious: the horses cannot by possibility pull exactly together, however nicely they may be matched in point of size and strength. This will hold good in the case of two, and much more in the case of a greater number; so that the greater the number in every horse team, the greater the expense of every pound weight that that team pulls along. This is a disadvantage in the employment of combinations of small animals of which no ingenuity and skill can get the better; and though it is not very apparent in countries which are intersected in every direction by roads planned on the most scientific principles and executed and kept in repair in the best manner (which might be, if it is not, the case in England); yet if we are to suppose a country where such roads cannot be generally made or maintained, then we can understand something of the value of such an animal as the elephant.

There was a time when most of the merchandise and produce, which was carried inland in England, had to be carried on pack horses; and then if the distance was a hundred miles, or even fifty, the price of the carriage was nearly equal to that of the common produce of the earth; and thus, the several districts of the country were cut off from each other; and it was no uncommon occurrence for the people of one district to be dying of famine, while there was an abundant surplus in another district, but no means of fetching that surplus to the needy of which the expense could at all be borne.

India is a country which from its geographical formation, its physical character, and its vast extent, can never be intersected by wheel-carriage roads as England is. In the first place taking the mere extent, the wealth of the world would not suffice for making the requisite length of roads for such a country. In the second place, the transition from the lower districts to the higher in southern India is so abrupt, that wheel-carriage roads are in many instances entirely out of the question; so much so that after the British armies had laboured as much as they could at the making of such roads, they found it necessary to dismount their guns from the carriages, and call in the assistance of the elephant to pull them up. In the third place, the rains in India, when they do come, come with such violence, especially upon the steep slopes where the construction of roads is most expensive, that they uproot the trees and tear the rocks in pieces, and of course no road, let it be constructed as it may, could withstand the violence. Many places of India must therefore, of necessity, always remain what we may call a burthen country; and as either for a carriage on the back, or a dead pull, an elephant concentrates into one effort a power equal to that of a great number of other animals, the elephant must become more valuable in India, in proportion as the country improves. Since the British ascendancy was complete, India is in a fairer way to improvement than it ever was at any period of its history, long as that history is. It is now safe from those external invasions by which it was so often and so cruelly plundered in former times: and we may hope that it is equally safe from those internal commotions which were probably more calamitous and destructive. Thus, though India is among the oldest countries upon the historic record, it is what may be

called an infant country in respect of the reciprocal intercourse of its different districts for the welfare of the whole.

It is on this account that, with reference to India, the elephant has become more interesting than it was at any former period. In the mere parade of an army, or in the march of a nabob, it may be a piece of gorgeous folly; but if it can be employed to fetch from one district that which shall relieve the wants of another, and stimulate, and by stimulating reward, the industry of both, then the elephant takes a higher rank in the scale of utility than has hitherto been given it, even by those who have doted and dreamed about its rational powers, and even were those powers real, they would sink it to nothing in comparison of the usefulness of the animal as a beast of burden, to India in a state of union and general industry. It is from a feeling of this kind that we have been induced to go a little more into the history of this noble animal, (and viewing it as an animal it is truly a noble one,) than we otherwise might have done; and this will justify us in adding a little more, in order to remove a pretty general prejudice that there is against the elephant, on account of the supposed length of time which it harbours revenge, and the indignity it feels at being made subservient to the use of man. So far as we have been able to carry our observation and experience, nature bears out the declaration of Holy Writ that the dominion of man over the rest of the world is universal; and that, whenever he fails in it, it is in consequence of his own ignorance—ignorance either of the proper use of the creature, or of the means of applying it to that use.

For the means of demonstration here we must again have recourse to the grand authority for rational information on the subject of the elephant, Mr. Corse Scott; and we have the less hesitation in doing so, that while Mr. Scott conveys nothing but the truth, and no truth but that which is really and practically useful, he contrives at the same time to make all his statements very pleasant reading; so that his plain matter-of-fact has more charm in it than the romance of almost any other man. "In June 1787," says Mr. C. Scott, "Jalra Mungul, a male elephant taken the year before, was travelling in company with some other elephants towards Chittagong, laden with a tent and some baggage, for our accommodation in the journey. Having come upon a tiger's track, which elephants discover readily by the smell, he took fright, and ran off to the woods, in spite of the efforts of the driver. On entering the wood, the driver saved himself by springing from the elephant and clinging to the branch of a tree under which he was passing. When the elephant got rid of his driver, he soon contrived to shake off his load. As soon as he ran away, a trained female was despatched after him, but could not get up in time to prevent his escape; she, however, brought back his driver, and the load he had thrown off, and we proceeded without any hope of ever seeing him again. Eighteen months after this, when a herd of elephants had been taken, and had remained several days in the inclosure, till they were enticed into the outlet, then tied and let out in the usual manner, one of the drivers, viewing a male elephant very attentively, declared he resembled the one which had run away. This excited the curiosity of every one to go and look at him; but when any person came near, the animal struck at them with his trunk, and, in every respect, appeared as wild and

outrageous as any of the other elephants. At length an old hunter coming and examining him narrowly, declared that he was the very elephant that had made his escape about eighteen months before. Confident of this, he boldly rode up to him on a tame elephant, and ordered him to lie down, pulling him by the ear at the same time. The animal seemed quite taken by surprise, and instantly obeyed the word of command with as much quickness as the ropes with which he was tied permitted; uttering, at the same time, a peculiar shrill squeak through his trunk, as he had been formerly known to do, by which he was immediately recognised by every person who had ever been acquainted with this peculiarity. Thus we see that this elephant, for the space of eight or ten days during which he was in the inclosure, and even while he was tying in the outlet, appeared equally wild and fierce as the boldest elephant then taken, so that he was not even suspected of having been formerly taken till he was conducted from the outlet. The moment, however, he was addressed in a commanding tone, the recollection of his former obedience seemed to rush upon him at once, and without any difficulty he permitted a driver to be seated on his neck, who, in a few days, made him as tractable as ever."

This account of the sagacity of the elephant we shall conclude, by quoting some of those stories which have been commonly related as illustrative of the degree of intellect which he is supposed to possess, for the purpose of gratifying the general reader. In the eastern countries which are still under the controul of the native rulers, the elephant is sometimes exhibited in a manner similar to that in which wild beasts were on the arena of the Roman amphitheatres. We shall give one instance of an engagement between elephants and a tiger, in which great injustice appears to have been done to the latter animal. It is related by Mr. Finlayson, in his account of the mission to Siam and Hué, and took place on a grassy spot about half a mile each way; the governor, the mandarins, and the soldiers being present on the occasion. The tiger was bound to a stake in the centre of the plain, the claws being torn out, and his lips being stitched together. He was turned loose, and attempted to escape, but in vain: he next threw himself at length upon the grass, till, seeing a large elephant with long tusks approach, he rose and faced the coming danger. The elephant was, by this attitude, and the horrid growl of the tiger, too much intimidated, and turned aside; while the tiger pursued him closely, and struck him with his fore paw upon the hind quarter, quickening his pace not a little. The elephant being brought back to the charge, rushed on furiously, driving his tusks into the earth under the tiger, and, lifting him up, cast him about thirty feet. The tiger lay as if dead, yet he had sustained no material injury; for, on the next attack, he threw himself into an attitude of defence, and, as the elephant was again about to take him up, he sprung upon his forehead, fixing his hind feet upon the trunk of the former. The elephant was wounded, and so frightened that he fairly ran off, and could not be rallied to the fight again. Another elephant was now brought, but the tiger made less resistance, it being evident that the tosses he received must soon occasion his death. Other elephants with tusks were brought forward: their attack was in every instance by rushing upon the tiger, thrusting their tusks under him, and throwing him to a distance. Of their trunks they were evidently very careful, rolling them cau-

tiously under the chin. When the tiger was perfectly dead, an elephant was brought up, who, instead of raising him with his tusks, seized him with his trunk, and cast him to the distance of thirty feet.

Elephants in India were once employed in the launching of ships. One was directed to force a very large vessel into the water, but which proved superior to his strength. In a sarcastic tone of voice his master desired the keeper to take away the lazy beast, and bring another in his stead; the distressed animal instantly increased his efforts, in doing which he fractured his skull on the spot.

An elephant in Delhi, passing along the streets put his trunk into a tailor's shop, where several people were at work; one of them pricked the end of it with his needle. The beast passed on; but in coming to the next dirty pool of water filled his trunk with it, and returned apparently in great wrath back to the shop, where, upon arriving, he discharged the whole contents over those who had offended him, and entirely spoiled their work.

An elephant in Ajmeer, which passed frequently through the bazaar or market, as he went by a certain herb woman, always received from her a mouthful of greens. At length he was seized with one of his periodical fits of rage, broke from his fetters, and, running through the market, put the crowd to flight, and among others this woman, who in haste forgot a little child she had brought with her. The animal, gratefully recollecting the spot where his benefactress was wont to sit, laid aside his fury, and taking up the infant gently in his trunk placed it safely on a stall before a neighbouring house. In the Dekan, another elephant, not having received some arack which had been promised by the cornac, or governor, by way of revenge killed him. The cornac's wife, who was an eye-witness to this, took her two children and flung them before the elephant, saying, "Now you have destroyed their father, you may as well put an end to their lives and mine." He instantly stopped, relented, took the biggest of the children, placed him on his neck, adopted him for his cornac, and never afterwards would permit any body else to mount him.

There was a soldier at Pondicherry, who was accustomed, whenever he received his share of liquor, to carry a certain quantity of it to one of these animals, having drunk rather too freely one day, and finding himself pursued by the guards, who were going to take him to prison, he took refuge under the elephant's body and fell asleep. The guard tried to force him from this asylum in vain, as the elephant protected him with his trunk. The following morning, the soldier recovering from his drunken fit, shuddered with horror to find himself stretched under the belly of this huge animal. The elephant, which, without doubt, perceived the man's embarrassment, caressed him with his trunk in order to inspire him with courage, and made him understand that he might now depart in safety.

A painter was desirous of drawing the elephant, which was kept in the menagerie at Versailles, in an uncommon attitude, which was that of holding his trunk raised up in the air, with his mouth open. The painter's boy, in order to keep the animal in this posture, threw fruit into his mouth; but as he had frequently deceived him, and made him an offer only of throwing the fruit, he grew angry, and, as if he had known the painter's intention of drawing him

was the cause of the affront that was offered him, instead of revenging himself on the lad, he turned his resentment on the master, and taking up a quantity of water in his trunk, threw it on the paper which the painter was drawing on and spoiled it.

In Britain it was some time ago found necessary, in consequence apparently of the declining interest of the drama, as performed by human beings, to introduce the elephant on the boards as an actor; and whether we may consider that this introduction did or did not contribute to establish the taste of that nation which produced Shakspeare, the histrionic elephant became the most renowned actor of its time. A female elephant was thus made to take a part, in short to become an actor requisite to the plot of a dramatic performance at the Adelphi Theatre, several years since. Among her feats was that of uncorking and drinking several bottles of wine, and supping with her stage companions around her. Above all, she assisted the escape of some of the *dramatis personæ* from prison, by kneeling upon her hind legs, and thus forming an inclined plane for the safe descent of her friends; and this she did unmoved by the glare of numerous lights, the sounds of music, and shouts of the admiring audience.

Among the most interesting elephants kept in this country, without any reference to profit, was one which was lately at the Duke of Devonshire's villa at Chiswick. When a lady departed for India, she asked the duke in a sportive manner, what present she should send him from that land of marvels; and in an equally sportive mood, the duke replied, "Certainly nothing less than an elephant." The matter passed over, but in due time the present came, and as long as the elephant lived it was a very interesting animal. It was a female, perhaps not altogether full grown, but remarkable for the gentleness of its disposition; and from the kindness with which it was treated, and the free range that was allowed to it, it probably came nearer to an elephant in a state of nature than any other which ever appeared in this country. The house erected for her shelter was of large dimensions and well ventilated, and she had besides the range of a paddock of considerable extent. At the call of her keeper she came out of her house, and immediately took up a broom ready to perform his bidding in sweeping the grass or paths. She would follow him with a pail or watering-pot round the enclosure. Her reward was a carrot and some water; but previously to satisfying her thirst she would exhibit her ingenuity by emptying the contents of a soda water bottle which was tightly corked. This she did by pressing the bottle against the ground with her foot, so as to hold it securely at an angle of about forty-five degrees, and gradually twisting out the cork with her trunk, although it was a very little above the edge of the neck; then, without altering the position, she turned her trunk round the bottle, so that she might reverse it, and thus empty the contents into the extremity of the proboscis. This she accomplished without spilling a drop, and she delivered the empty bottle to her keeper before she attempted to discharge the contents of the trunk into the mouth. The affection of this poor animal for her keeper was so great, that she would cry after him whenever he was absent for more than a few hours. She was about twenty-nine years old when she died, early in the year 1829, which was understood to be of a pulmonary consumption.

We shall now very briefly notice the distinguishing characteristics of the several species of elephants.

In the INDIAN ELEPHANT, or more correctly the South Asiatic elephant, to which the chief part of the preceding observations apply (*Elephas Indicus*), the following are the general characters: the skull elongated; the forehead flat and even concave; the enamel which forms the cutting part of the grinders disposed across the teeth in a series of flattened ovals; the ears large; and five horny nails on each of the fore feet, and four on each of the hind. In this species the females, and in some varieties the males, also, have the tusks very short, and nearly straight; the ears of the female are smaller than those of the male, and the colour is dull grey speckled with brown, and occasionally with a little white; and species entirely white are mentioned, which are, in all probability, albinos, but which are held in great and even sacred regard by some of the natives.

In the East Indies, elephants as well as Hindoos, are divided into castes, only there are not quite so many of the former as of the latter. In Bengal, and we believe, generally, in those places of India where elephants are much used, they are divided into two castes: *Koomareah*, princely, or nabob elephants; and *Merghee*, or hunting elephants. The *Koomareah* or nabob race is a deep bodied, compact, and very strong animal, having a very large trunk (which is always esteemed a great beauty in an elephant), legs short, but thick in proportion to the size of the animal. This variety is preferred, as it is of superior strength, can undergo much greater fatigue, and carry heavier burdens than the others: an elephant of the *Merghee* cast, when full grown, is generally taller than the former, but has not such a compact form; his legs are longer, he travels faster, has a much lighter body, and his trunk is both short and slender in proportion to his height. There appears no predilection in any of these elephants to have exclusive connection with his own particular caste, and hence the mixed breed is held in greater or less estimation, in proportion as it partakes of the qualities of the *Koomareah*, or *Merghee* caste. In some elephants the tusks are large, as in the variety named *Dauntelah*, in which they generally project forwards, and curve upwards. In the variety termed the *Mooknah*, the tusks are very small and straight, and point almost directly downwards.

This species of elephant is said to be perfect when the ears are large and rounded, but not so if the ears are ragged and indented at the margin; his eyes are of a dark hazel colour, and free from specks; the roof of his mouth and tongue are without dark spots of any considerable size; his trunk large, his tail long with a tuft of hair at the extremity, reaching nearly to the ground. There must be five nails on each of the fore feet, and four on each of the hind ones, making in all eighteen; he carries his head high: the arch or curve of his back gradually rising from the shoulder to the middle, descending from thence to the insertion of the tail.

The species now under notice is peculiar to the low grounds of Asia, southward of the central mountains; though it is not confined to the main land, but is found abundantly in many of the islands, and especially in Ceylon. In the more remote islands of the eastern sea, it is not met with, nor is there a single vestige of it, or of its bones, in the whole extent of Australia. Indeed, it is worthy of remark, that while

the bones of the fossil elephant of the north, of which, probably, not a single specimen has been alive since the historic record commenced, are found in such numbers, the bones of the living elephant should rarely be met with. No doubt there is a much stronger conservative principle in the cold atmosphere of the north than in the warm one of the south, especially where that atmosphere is humid as well as warm, as it is in all the places which are inhabited by elephants; and, perhaps, when we consider that in the elephant countries the action of the weather alone suffices in brief space to crumble buildings of stone into heaps, we should in all probability not wonder very much, though it should speedily reduce the bones even of elephants to their constituent earths.

**AFRICAN ELEPHANT** (*Elephas Africanus*). In its general aspect, this species does not differ very much from the former. Its leading characters are: the skull rather shorter than in the Indian species; the forehead rounded, and protuberant in the middle rather than hollow; the enamel in the grinders formed into a sort of lozenges, which are larger and fewer in number than those in the teeth of the Indian elephant; the ears are also larger, rise up much higher above the general line of the head, and extend farther backwards, so far, indeed, as to reach and partially to cover the shoulders. The tusks of this species are perhaps larger in proportion than those of its Asiatic congener, and they are of more equal size in the two sexes, those of the female being nearly equal in size to those of the male. The tusks are also of more compact texture; so that African ivory is of more value than Asiatic, as being susceptible of a finer polish, and also stronger. We believe that there are some rare instances in which the strength of this animal has been pressed into the service of man; but they are exceedingly rare, and the animal must still be considered as a free tenant of the forest. It is found in all the rich and wooded countries, from the Cape of Good Hope to the Desert of Sahara, but not to the northward of the Desert, or in Egypt, or indeed in any part of the valley of the Nile, or at least of Sennar, to the northward as far as the Abyssinian mountains. The elephant indeed is but ill adapted for climbing heights, from its great weight; and therefore we may naturally suppose, that as a southern animal it must be bounded by such mountains as those which we have mentioned.

The African elephant is inferior in size to the Asiatic; but it seems rather more hardy. It is equally remarkable for the acuteness of its sense of smelling; and some remarkable instances are told of its powers in distinguishing enemies. As it is hunted for destruction much more than the Asiatic elephant, it is probably rendered more ferocious by this means; though it is not very easy to see upon what principle the destruction of one animal in hunting should make others of the same race more fierce towards the hunters. It is for the sake of its tusks chiefly that this elephant is hunted in the vicinity of the Cape; though the Hottentots eat the carcase with zest; and the ears, which are very strong as well as large, are made use of as a sort of sledge. We shall give the substance of one or two anecdotes from Sparrman, as illustrative of the character of this animal. The first shall be that of two farmers or boors, who began the occupation at once without any training. On the evening the wild elephant was observed, they

resolved to pursue it on horseback, though it was the first time they had ever seen one. Their horses, though equally unaccustomed to the sight as their riders of this gigantic-like animal, yet were not in the least frightened; nor did the elephant indeed appear to give himself any trouble about them, until they were within seventy or eighty paces of him. At about that distance, one of the party, agreeably to the usual manner of the Cape huntsmen, leaped from his horse, and fastening the bridle dropped on one knee, and with his left hand sticking his ramrod into the ground rested his gun upon it, took his aim, and fired at the elephant, which had then got about forty or fifty paces further off; for when they hunt the larger kind of animals in this country, they generally choose the opportunity of firing at the distance of from 100 to 150 paces, both because they load their pieces in such a manner that the ball may, as they think, do more execution at that distance, and that they can also gain time to mount their horses again and ride off before the wounded animal can make up to them to take his revenge. Our sportsman had scarcely got into the saddle, and turned round his horse's head, before he ascertained that the elephant was at his heels. At this very instant the animal set up a shrill piercing cry, which he imagined to pierce to the very marrow of his bones, and which occasioned his horse also to make several hasty leaps, and then gallop off as fast again as before. In the meantime, the huntsman had sufficient presence of mind to ride his horse up an ascent, well knowing that elephants and other heavy animals are unwieldy and slow in ascending up a hill, in proportion to their weight, and the reverse in descending a hill. By this means, he not only more certainly distanced his antagonist, but his companion had more time to advance on one side of the elephant, where he imagined he could most easily direct the shot at the heart, and the larger arteries connected with the lungs of the animal. This shot did not, however, hit in any dangerous part, as the horse was rather unruly, and pulled at the bridle, which the man had hanging over his right arm, at the instant that he jumped off his horse and discharged his piece in the same manner as the former had done. This now turned the elephant upon this last antagonist, but he was soon wearied of pursuing him, as the sportsman had an opportunity of riding away from him up a still much steeper hill than his companion.

The two hunters now found that it would suit their purpose better to hold each other's horses, so that they need not get off; while each of the sportsmen fired their pieces by turns. The elephant, even after the third ball, still threatened vengeance; but the fourth shot had the effect of reducing his violence, although he did not fall till he had received the eighth one. Of course none of the balls aimed at him had taken effect in a part immediately vital, because when struck there the elephant will fall at a single shot. We shall mention one other anecdote of the pursuit of this animal; and we give it because it is illustrative of the acuteness of the animal's sense of smell. It was related to Sparrman by a hunter of the name of Dirk Marcus, of course a Dutchman. "Once," says Dirk, "in my younger days, when from a hill covered with bushes near a wood I was endeavouring to steal upon an elephant to the leeward of me, on a sudden I heard a frightful cry or noise from the lee side, and although I was at that time one of the boldest elephant hunters in that

country, I must confess I was in a terrible quaking, so much so that I believe the hairs on my head stood quite erect. At the same time it appeared to me as though I had several pails of water thrown over me, without my being able to stir from the spot, until I saw this huge creature so near me that he was almost on the point of laying hold of me with his trunk. At that instant I fortunately had the presence of mind to take to my legs, and to my no small astonishment I found myself so swift that I thought I hardly touched the ground. The beast, however, was pretty close upon my heels; but having at last got to the wood, and crept away from him under the trees, the elephant could not easily follow me. I am quite certain that he could not see me in the place where I was at first, and that therefore he must have found me out by the scent." So much for the escape of Dirk Marcus, the Dutch boor, whose story no doubt contains a good deal of the marvellous. Indeed it is not an incurious matter in the history of mankind, that while, upon all ordinary subjects, the Dutch are the most matter-of-fact people on the face of the earth, they are the greatest romancers in matters of adventure and of natural history; and it is possible, indeed probable, that more unfounded but marvellous stories of this kind originated with the early Dutch navigators than with any other people on the face of the earth.

But even Dirk Marcus was probably not so brave an elephant hunter as the wild bushmen of the Cape, whom the Dutch settlers used to be as zealous in hunting and shooting in cold blood, as they were in hunting elephants, or in carrying on a campaign of extermination against the antelopes. The bushmen not only shoot elephants with their poisoned arrows, but come to close quarters with their assagais or spears, with which they stick the great animal all over till he is bristled like a porcupine, and the pain often causes him to accelerate his own death; as from his natural instinct of falling upon and crushing the lion, when it springs on the hinder part of his body, he falls upon the spears, and by this means pushes them home to his vitals. When the inhabitants of one of the kraals or villages of those rude people catch an elephant, it is a day of as much joy as when the Greenlanders capture a whale. The flesh of the elephant is cut up in ribbons, as is done with beef in South America, and in many parts of Old Spain; and this elephant beef, by being suspended in the open air, and dried in the intense heat of the sun, can be kept for a considerable time, and is said not to be very unpalatable. The trunk is an especially delicate morsel, because the muscles in it, though very numerous, are small, and much more delicate in their fibres than the common muscles of motion in the body of the animal. The feet, also, are very much prized, though chiefly on account of the cartilaginous substance on the soles. To a European, however, an elephant feast would, probably, be but a sorry meal.

Independently of his living only in the wild state, and inhabiting woods of more savage character than those of Asia, there is a sullenness in the air and expression of the African elephant. His head is carried much lower, and less gracefully than that of the Asiatic species; and the apparent shortness of the face, the want of squareness in the outline, and the bullet-shape of the cranium, all conspire to take off from him that expression of sagacity which is, probably, more imaginary than real in his oriental congener.

The greater size of the tusks, too, in proportion to that of the animal, tends to increase this expression. But notwithstanding all these disadvantages of appearance, the African elephant is a highly interesting as well as powerful animal; and one almost regrets that, even for the sake of bushmen feasts and ivory trinkets, he should have been hunted down with so much assiduity in those wild woods which, as they are not taken possession of by civilised man, might have remained as birthright pastures of the elephant. In consequence of this there are now few or no elephants except at a considerable distance from the Cape, though in the woods farther to the north they are still numerous.

THE FOSSIL ELEPHANT (*Elephas primigenius*). It is doubtful whether as much interest has not been excited, not among the students of nature only, but even by the mass of the inhabitants in those places where its remains are abundant, by this extinct animal, as by at least the African species of the living one. The characters are: the skull lengthened and the forehead concave, as in the Asiatic elephant; the under jaw much more obtuse than in either of the living species; the grinders larger, with the enamel disposed in transverse bands or ribands set closely together; and the sockets of the tusks much more produced than those of the others, as if these organs had some more laborious office to perform. This peculiar lengthening of the sockets, and general enlargement of the anterior extremity of both jaws, is conclusive evidence that the trunk of this elephant must have been thicker at its base or junction with the head; and renders it probable that, if not a more universal instrument, it may have been a more powerful one than the trunk of either of the existing elephants. From the skeletons, it is not probable that this lost animal was of taller stature than his living congeners; but from the enlargement of some of the processes of the bones, and various other circumstances connected with the skeleton, there is some reason for believing that it must have been of thicker body and more robust frame, than are the elephants which still exist. The following cut will furnish some idea of the skeleton of this animal; and any one who has seen a live elephant will feel no great difficulty in imagining it clothed with flesh.

It is not for what this animal has been in itself when alive, and acting its part in living nature, that it claims our attention; for it forms a curious section in the history of human belief, as well as in that of progressive zoology. If its remains had occurred only in those countries over which the conquests of the ancient

nations of the east, or even of the Romans, had extended, then the remains might have been considered as those of elephants which had been marched in the trains of the conquerors, at least until science had established those specific differences between them which are now so well made out.

But those remains have been found most abundantly in countries which, in all probability, the foot of southern conquest never trod; while in the range of that conquest, and especially that part of it where elephants were more likely to have accompanied the armies, these remains are unknown. It is not probable that any southern conqueror of early times ever crossed the Carpathian mountains, or the central marshes, or even the southern steppes of European Russia; and it is equally improbable that any such conqueror ever crossed either the central desert of Asia or the Altaian ridge, so as to penetrate into Siberia; and yet it has been found that the remains of those elephants are so numerous in many parts of that country, that they form large banks, and almost entire islands, in the lower parts of the great rivers near their confluence with the Polar Ocean. These are so numerous, and the tusks are in a state of such preservation, that they form an article of commerce as ivory. It is true that for a long period the natural history of Siberia was very little known, and the vast number of the remains of the fossil elephant there were known only to the few savage hordes who carry on their hunting during the summer in those dismal wastes; and it is still more recently that those remains have been either found in an entire skeleton with their natural connections, or that men sufficiently skilled in comparative anatomy have joined them bone to bone, in the same relative situations which they must have held during the lives of the animals.

Previous to this period they had been found in various parts of Europe, indeed partially in all parts of it, from the shores of the Mediterranean to those of the Icy Sea; on the main land, most frequently in the lower valleys, or near the estuaries of the larger rivers. But they were not confined to the continent, for they were observed in the British Islands, and even in Iceland, distant as that island is from the European shores; but how they found their way to such remote places is a point which has not been and which probably cannot be determined.

Before science was applied to the rational solution of natural phenomena, those bones gave rise to singular conjectures. Where only a bone or two was met with, these were, generally speaking, considered as human bones, as the remains of some giant race which had peopled the world in times anterior to all memory. This belief accorded well with the superstitions of the northern nations; who are still inclined to ascribe the erection of every ruin of which the history is lost, as well as the production of many of those singular appearances which rocks and the other permanent works of nature exhibit in these wild places, to the labours of the giants; but when it came so far as the finding of a tusk, of such dimensions as some of those fossil tusks are, it tended to upset the theory of the giants; for though many of these had "terrible teeth," according to the generally believed legends, the tusks of an elephant, weighing some sixty or seventy pounds each, were rather too much for a giant even of the first class.

In this way the bones were, in the course of time, acknowledged to be the bones of elephants; but as it

was not supposed, or even thought of, that elephants of a race now lost could ever have inhabited the cold regions in which those bones are most plentifully found, a new belief was taken up; and they were the bones of the present race of elephants which had been transported thither by some great convulsion of nature.

Nor was there any difficulty in finding out a convulsion sufficient for the performance of this transfer; for in those days the fact of a universal deluge was held perfectly sufficient for the solution of every difficulty which could not be solved by any other means; and if any thing, be it what it might, was found in the earth in a way that nobody could account for, then all perplexity was solved by the simple allegation that it had been "brought there by the flood." It never occurred to those resolvers of difficulties, that it was incumbent on them to inquire what a flood of water covering the earth could do; whether it could move large bones from the valley of the Ganges to the regions of the Pole; and especially whether it could place them in the situations in which they were found. When those things came to be thought of, it was soon discovered that the explanation by a deluge would not satisfy the question. The bones were placed in strata apparently deposited at different times, so that several floods would have been required; and the different bones of the same animal were found so near each other, that it was impossible not to see that the animal must have been brought entire to those situations in which the bones were found.

Of the fossil elephant the most perfect specimen, and the one which put us completely in possession of the anatomy of the animal, is that which was cast ashore, frozen up in an icy tomb, upon the north coast of Asia, about the close of the last century. In the year 1799, a Tungusian fisherman observed a strange shapeless mass projecting from an icebank near the mouth of a river in the north of Siberia, the nature of which he did not understand, and which was so high in the bank as to be beyond his reach. The next year, he observed the same object, which was then rather more disengaged from amongst the ice, but he was still unable to conceive what it was.—Towards the end of the following summer, 1801, he could distinctly see that it was the frozen carcase of an enormous animal, the entire flank of which, and one of its tusks, had become disengaged from the ice. In consequence of the ice beginning to melt earlier, and to a greater degree than usual, in 1803, the fifth year of this discovery, the enormous carcase became entirely disengaged, and fell down from the ice-crag on a sand-bank, forming part of the coast of the Arctic Ocean. In the month of March of that year, the Tungusian carried away the two tusks, which he sold for the value of fifty rubles; and at this time (says Cuvier, whose relation we quote) a drawing was made of the animal, of which I possess a copy. Two years afterwards, or in 1806, Mr. Adams went to examine this animal, which still remained on the sand-bank where it had fallen from the ice; but its body was then greatly mutilated. The Tungots of the neighbourhood had taken away considerable quantities of its flesh to feed their dogs; and the wild animals, particularly the white bears, had also feasted on the carcase: yet the skeleton remained quite entire, except that one of the fore legs was gone. The entire spine, the pelvis, one shoulder-blade, and three legs, were still held together by their ligaments, and by some remains of the skin;

and the other shoulder-blade was found at a short distance. The head remained covered by the dried skin, and the pupil of the eye was still distinguishable. The brain also remained within the skull, but a good deal shrunk and dried up, and one of the ears was in excellent preservation, still retaining a tuft of strong bristly hair. The upper lip was a good deal eaten away, and the under lip was entirely gone, so that the teeth were distinctly seen. The animal was a male, and had a long mane on its neck. The skin was extremely thick and heavy, and as much of it remained as required the exertions of ten men to carry away, which they did with considerable difficulty. More than thirty pounds' weight of the hair and bristles of this animal were gathered from the wet sand-bank, having been trampled into the mud by the white bears while devouring the carcase. Some of the hair was presented to our Museum of Natural History, by M. Targe, censor in the Lyceum of Charlemagne. It consists of three distinct kinds. One of these is stiff black bristles, a foot or more in length; another is thinner bristles, or coarse flexible hair, of a reddish brown colour; and the third is a coarse reddish brown wool, which grew among the roots of the long hair. These afford an undeniable proof that this animal had belonged to a race of elephants inhabiting a cold region, with which we are now unacquainted, and by no means fitted to dwell in the torrid zone. It is also evident, that this enormous animal must have been frozen up by the ice at the moment of its death. Mr. Adams, who bestowed the utmost care in collecting all the parts of the skeleton of this animal, proposes to publish an exact account of its osteology, which must be an exceedingly valuable present to the philosophical world. In the meantime, from the drawing (says Cuvier) which I have now before me, I have every reason to believe that the sockets of the teeth of this northern elephant have the same proportional lengths with those of other fossil elephants, of which the entire skulls have been found in other places. Many curious and important facts are presented by the geographical distribution of remains of this species. They have been dug up in most of the countries of Europe, from the Mediterranean sea to the Arctic circle. The greatest abundance of them occur in Asiatic Russia. In the European isles they have also been found, in Iceland, and several parts of Great Britain and Ireland; and their bones have even been dug up in North and South America, and in Hudson's Bay. We have given these particulars of the fossil elephant, as well as of the living ones, rather more at length than we can afford to do in the case of most subjects, partly on account of the direct interest of the subjects themselves, and partly because of the mistakes respecting them, which are still current among many people.

**ELEPHANT'S FOOT** is the *Testudinaria elephantipes* of Burchell. It is a native of the Cape of Good Hope, and remarkable for having the collet or crown of the roots swollen to a very large size, and covered with a tessellated bark of very curious structure. Both roots and stems are comparatively slender and fugitive; but the tuberous body is very durable, there being some individuals at the Cape which indicate two hundred years growth. A new layer of liber being added every year, these may be easily counted on the edges of the fractured portions of the exterior surface.

**ELEPHANTOPUS** (Linnæus). A genus of West Indian herbaceous perennials, met with in stove col-

lections, but of no great beauty. It belongs to *Compositæ*, and is easily propagated by cuttings struck in sand.

**ELICHRYSUM**, an exploded genus of plants of Willdenow's, now included in that of *ASTELMA*, which see.

**ELK**. See the article **DEER** for a full description of this animal.

**ELLIPSOSTOMATA** (De Blainville). This forms the third family of the second order *Asiphronebranchiata*; second class *Paracephalophora*. The general character of the shells forming this family is that of possessing a longitudinal oval aperture, sometimes transversely and completely closed by a calcareous or horny operculum. The form of these shells varies, and they are generally smooth. The family is constituted of the genera *Melania*, *Rissoa*, *Phasianella*, *Ampullaria*, *Helicina*, and *Pleurocerus*.

**ELMIDÆ**. A family of minute coleopterous insects belonging to the section *Pentamera* and subsection *Philhydrida*, being of short form, and having the legs formed for crawling, and the tarsal claws large; the palpi are short and the head inflexed. There are two genera, *Georyssus*, Latreille, and *Elmis*, (Linnæus, Müller), of which the species are found under stones at the bottom of running brooks. In this situation the larvæ also reside. The writer has taken some of the species of *Elmis* from stones in water a yard deep. The structure of the organs of respiration of these sub-aquatic species offers a very interesting subject of research.

**ELM TREE** is the English name of the different species of the genus *Ulmus* of Linnæus. The elm is one of our principal timber trees for usefulness, ranking next to the oak. There are nineteen species already described, six of them marked as natives of Britain. The most valuable of all, *U. campestris*, the common English elm, although completely naturalised, is certainly not a native, as it is never met with in forests, nor ever far from buildings, or marking the place where buildings have formerly stood. Neither does it ripen seeds in this country, showing that it is a native of a warmer climate.

It has been stated that the English elm was introduced into this country from Palestine during the crusades; but however this might have been, it is very probable, from present appearances, that there was once a time when it was very fashionable to plant this tree. The oldest and finest specimens are met with in the near neighbourhood of palaces, noblemen and gentlemen's country-seats, and dotted over the hedge-rows belonging to these residences. Sometimes we see them shading the old manor-house, or sheltering the farm homestead, formerly the abode of the wealthy yeoman, though now of a tenant who cares nothing about trees.

Elm timber is less durable than oak, either standing or after being converted to use. The tree arrives at a great height with proportionate diameter of stem; but after three or four score years, especially on light soils, the bole begins to decay at the heart, and which decay proceeds rapidly outwards till the trunk becomes a mere shell, in which state it will, however, live and be increased in diameter for many years, although quite hollow within.

This species is a very ornamental tree in all its stages, more especially after it has acquired its natural character and specific habit, and the older it is the more picturesque it becomes. When planted for

profit it should be felled as soon as a load (fifty cubic feet) or a load and a half of timber is computed to be in the bole. Better it is to fell a few years too soon than one too late. One invaluable property of the English elm is its tendency to stool, that is, to produce suckers from the root, which fully compensates for its want of seed. Where once a tree is planted, particularly in hedge-rows, there it and its young progeny will ever remain. And it is no uncommon case that the same hedge-row has been felled from by the grandfather, father, and son, and yet the last cannot perceive any diminution in the number of his trees.

This tree is best propagated by layers. It is sometimes grafted on the common or witch elm; but this is a bad practice, because there can be no succession of suckers of the right sort.

Middlesex is famous for hedge-row elms; and there the trees are most unmercifully shredded, that is, trimmed up and divested of all their side branches except a few at the top. This, though it causes the timber to be of a knotty unwedgable character, is apt to induce internal decay from the numerous wounds inflicted on the surface, some of which, if not quickly healed over, admit moisture which penetrates to the centre, or allows a discharge of sap, a defect to which the elm is very subject.

There are several other species of elm, natives of Britain and North America. The witch elm, a very common sort, is of a more rambling growth than the first, but the timber is less esteemed, though very useful for many purposes in rural buildings and implements. The cork-barked and Dutch elms are admitted into our plantations for the sake of variety only. The leaves are an ingredient in the "British herb" tea, so much of which was lately condemned and burnt by order of the commissioners of customs. The inner bark of the elm, like that of many other trees, has been, in times of scarcity, and still is commonly in the northern parts of Europe, ground into powder and mixed with meal to make a coarse kind of bread. The leaves form a good nourishing kind of fodder, and in many parts of this island they are given to cattle.

**ELYMUS** (Linnaeus). A genus belonging to the natural order *Gramineae*, containing above twenty species, most of which are found in the northern hemisphere. Three of them are common in England, and called lyme-grass. One of them, *E. arenarius*, is cultivated on the sea-coast for fixing drifting sands.

**ELYSIA** (Risso). A genus of mollusks established by Risso, and inhabiting the Mediterranean, but too imperfectly known to be at present depended upon from his description, and probably referable to some genus already accurately described.

**EMARGINULA**—Lamarck; **PATELLA FISSURA**, Linnaeus. Lamarck has constituted this genus of molluscs from the confused genus of the Linnaean patella. This shell is conical, more or less elevated, and inclined to the anterior side, which is always the least, and, opposite to the slit or fissure, elegantly cancellated with longitudinal ribs and transverse striae, a deep and narrow marginal fissure extending nearly half-way to the summit; the interior, with a muscular horse-shoe impression, opens backwards, and is thicker at its origin. Most of the shells of this genus are very small, some are of an elevated, and others of a widely depressed conical form. Lamarck only enumerates two species, but more are now known. The animal

has an oval body, the mantle furnished with very delicate tentacula, placed round its circumference; slit more or less deep at the front part, for the communication with a very large bronchial cavity, in which the branchiae are distinctly visible. Taking the marginal fissure and its position with regard to the other parts of the shell, very distinct species may be distinguished; but it is scarcely necessary to enumerate them in this place, as they would only interest those naturalists who seek more deeply for minute distinctions than the generality of our readers are supposed to require. These shells belong to the second class *Paracephalophora*, second order *Cervicobranchiata*, first family *Retifera*.

**EMBERIZA**—Bunting. A very numerous genus of birds, belonging to Cuvier's great order, *Passeres*, and to the *Conirostral*, or cone-shape billed division of that order, of which, in as far as the form of the bill is concerned, they are very typical. This genus has been extended by some authors to include a vast number of birds, especially foreign birds, which from time to time were imported in single specimens, unaccompanied by any descriptions of their habit, and named without much regard to the proper distinctions of the buntings. Many of these, more especially the American ones, have been so well described, and are so popularly known as buntings, that we shall retain them, although *strict* regularity of system would justify our describing them under other names.

Bunting.

The general characters of this genus are these: bill very strong, short, straight, conical, compressed in the sides, firm in the cutting edges, but without any tooth or notch. The upper mandible narrower than the under one, turned inward at the edges, and with a hard or horny knob at the palatal end. It is in this bill that the true character of the bunting consists; and every bird which has such a bill may be regarded as a bunting, whatever may be its other characters. This bill is well fitted for the breaking of shells or the rinds of seeds, and ejecting them without losing any of the farinaceous kernel, which, from the way that the mandibles close, drops into the bill rather than out of it. The wings are moderately long, the second and third feathers being the longest, the tail forked or lobed, and spreading out towards the

extremity. The feet, with three toes before and one behind, all free. The resident species have their claws short and hooked, and adapted for perching on trees, and also on the culms and stems of those herbaceous plants from which they pick the seeds. This genus live chiefly upon seeds, and consume a vast quantity, seeking them indiscriminately upon the plants that produce them, or on the ground; but they likewise eat insects. The snow-bunting runs on the ground, but does not perch. It has the claw, as in the larks, with the hinder toe produced, or rather intermediate between the larks and the other buntings. This genus of birds have plenty of voice, but no song; and as their vegetable food is better seen in clear light, during the heat of the day, they are always active, and incessantly keep up a harsh and tuneless clattering. The air of these birds is heavy, and they are careless, and very easily snared by the fowler. In the autumn they get very fat, and the flesh of some of them is highly prized. The common bunting has rather a sober plumage; but the others are equally remarkable for the richness of their tints and the beauty of their contrasts. Their want of song prevents them, however, from being sought after for the cage, so that they are neglected, and persecuted as creatures formed merely for destroying or being destroyed. It is true, that where small seeds are sown and cultivated, the buntings commit considerable ravages; and they likewise consume a portion of the corn, especially of any patches that get ripe before other parts of the field; but during the rest of the year they are of considerable service in consuming the seeds of the larger weeds which grow in the fields, such as corn-marigold, ragwort, and other pests of thin and badly-cultivated soils, though they are not very welcome visitants in the garden. When seed time and harvest are blended together throughout the year, and seeds are sown at all seasons, the wild birds, which remain true to the seasons, while man forces his cultivation against them, are in so far mischievous; but in places where there are only seasonal crops, that is not so much the case. The time at which the granivorous birds are undergoing their moult is when the crops are or should be ripe; and as the smaller seeds are preferred by all the little birds to grain, and of course stubble lands to those which have standing crops, against the time that they congregate in flocks there should be always stubble for them.

THE YELLOW BUNTING (*Emberiza citrinella*), Yellow Bunting, Yellow Hammer, or Yellow Yowley.—This species has the tail-feathers blackish, the two outer ones on the inner webs marked with one acute white spot. The weight of the yellow bunting is, in ordinary, about seven drachms, the length six inches three lines, and the extent of its wing nine inches two lines. It is an inhabitant of Europe from its southernmost point, at least as far north as Soudmor, and it is likewise found in the west of Siberia. In this and many other countries it is of very common occurrence. Its song is as little attractive as that of the common bunting, consisting merely in a repetition of the same note five or six times, and terminating in a more lengthened and shrill one. But, besides their native note, it has two particular calls, the one that of rallying, which it in common utters when flying, and during summer on the approach of evening; and the other expressive of its uneasiness when alarmed or offended, especially when any one goes near its nest or little ones. Many of them are supposed to travel

southward during the autumn; but those which remain congregate in winter, mingling with chaffinches, sparrows, and many other small birds, approaching houses in the day time, or even towns, or frequenting high-ways, picking up little grains, and extracting them from horses' dung. This combination of different species, intent on catering, only lasts during the day; for some hours before nightfall the family separate, and retire to their respective haunts, the buntings previously perching on the tops of trees, from which they do not descend till after sunset. The male, from this elevation, pours forth his note in the season of love, sometimes for hours together, remaining without changing its position. During the spring and summer months, they frequent hedges and copses, but very seldom the interior of forests. They alight very suddenly from their flight, which is very rapid, and for the most part amidst thick foliage. The female bunting does not breed till late in the spring, and yet has two, and occasionally three, hatches in the course of the season. The nest, which is large and flat, and rather simply composed, is generally placed near the ground, sometimes under a clod, but more frequently in some low bush or hedge, and consists of straw and various dried stalks, lined with fine grass and long hair. The eggs vary in respect of colour and size, some being nearly white, and others having a purplish hue, but all more or less marked with hair-like streaks, and terminating with a roundish speck; and their number varies from three to five. The female incubates with such ardent attachment, that she may frequently be caught by the hand. During the short period she is absent in search of food, the male takes her place in the nest. The young are fed with small seeds and insects. These birds in captivity will live for six or seven years, and even longer; but they are liable to epilepsy; and their music is too little engaging to repay the trouble of rearing them. Where small birds are used for the table, as almost every description of them are in Italy, the yellow bunting is frequently fattened for the market. In flavour it very much resembles the lark.

The yellow hammer is one of the most common of British birds, and it is also one of the most beautiful; but somehow or other it is not a favourite; and, in very many parts of the country, the boys seek its destruction as a meritorious work.

THE COMMON BUNTING, or CORN BUNTING (*E. miliaris*), is more a bird of the cornfields and hedges, and less of the copses than the yellow bunting; and is considered, perhaps unjustly, as a great enemy to the farmer. This species is found throughout Europe and the northern countries of Asia, is not distinguished either for its song or the beauty of its colours, and has not so good a title to be admitted into the house as the preceding. It has a very similar plumage to that of the skylark, but surpasses it in size, being seven inches and a half in length, of which the tail measures three. The beak, measuring six lines, is strong, yellowish on the under part in the summer; and grey brown during the rest of the year; the feet, which stand six lines in height, the same. The general tint of the plumage is pale, reddish grey on the upper part of the body, and yellowish white on the under, speckled like the lark's with blackish brown spots, broader on the back and narrower on the belly. The quill-feathers are dark-coloured, as also the tail-feathers; the outer ones have a wedge-shaped but indistinct spot of white.

On many parts of continental Europe, the common bunting is a migrant; but in most parts of the British islands it is resident the whole year, though it flocks upon the lower fields during the winter, and lives more dispersedly in the breeding season. In the Shetland Islands, it appears in small flocks as a migrant during the winter; but as the spring sets in, and the nesting time approaches, it entirely leaves those islands, and is not found upon them again during the summer and autumn. It evinces a preference to champaign countries that abound in corn and meadows, being very rarely found in uncultivated tracts, or even in grass fields that are far from arable land. It may frequently be seen on the highest part of a hedge, or uppermost branch of a tree, uttering its dissonant and harsh cry, which it repeats at short intervals. These birds in this situation may be seen and heard during the greater part of summer, after which they may be met with in flocks, and continue so during the greater part of winter. At the time the female is busied with incubation, the male sits on a neighbouring tree, and cheers her with his rude song, taking her place occasionally at noon, when she is said also to sing, perched in her turn. The nest is placed among tall herbage, on the ground, or else in a very low shrub, about four or five inches above the surface of the soil, formed externally of straw, lined with fibrous roots, or dry grass, and occasionally finished with wool or long hair. There are from four to six eggs, of a dirty white, spotted and veined with reddish-brown and ash-colour. The young quit the nest before they can fly, being fond of running on the ground, and the parents continue to guard and feed them till they are fledged; but they not unfrequently betray them from their anxiety for the safety of the brood; and if a person happens to approach near the spot, they wheel round his head in a doleful manner. They are sometimes brought into the market and sold for larks, and, as an article of food, are not inferior to them, but they may easily be distinguished by the form of the bill and the tooth-like knob which they have on the palate. The fat birds are reckoned a great delicacy, but when they get old they are lean, dry, and very tough. They are fattened in Rome in the same manner as the millet. They are used by the bird-catchers in the autumn as call-birds, and they not only entice the foolish buntings into the snare, but different kinds of small birds; and they are put into low cages without bars or roosts for this purpose. As this species of bunting feeds its young, in great part at least, upon caterpillars, and as its winter food consists, in part, of the seeds of those plants which are most troublesome to the farmer as weeds, it is to be regarded as a serviceable bird, and not as a destroyer.

**THE FOOLISH BUNTING (*E. Cía*).** This species gets its name from the readiness with which it comes at the call of any other of the genus, more especially the yellow hammer, and the disposition which it has to go into any sort of trap or snare. In appearance it bears some resemblance to the common bunting, but it does not inhabit either exactly the same countries or the same districts. It is found in summer in the mountainous parts of southern Europe; and although it descends to the plains, and ranges at least as far as the middle of Germany in the winter, it is rarely seen near the coasts, and never, we believe, in the British islands. In size it is inferior to the yellow hammer being only six inches long, of which the

tail measures two and a half; the beak, five lines in length, is very sharp, blackish above, and of a greyish colour below; the iris is dusky; the legs are nine lines in height, and of a brownish flesh-colour. The head is grey, spotted with red, having small black streaks on the top, and an indistinct black line on the sides. The cheeks are light ash-colour; a dusky white streak passes from the nostrils above the eyes, a black one crosses them, and uniting with a third that springs from the under angle of the beak, encircles the cheeks; the back is reddish brown, speckled with black, the rump light red brown; the throat pale ash-colour, the under part of the neck, to the middle of the breast, grey, the rest of the under part of the body red, but the belly is somewhat lighter; the small wing-coverts are dark grey, the others are black; the anterior quill-feathers are edged with a reddish colour, the others, with the lowest row of the coverts, are red; the second row of the coverts have their points reddish white, which form a band of this colour on the wings; the tail, rather forked, is black, the two outer feathers have a wedge-shaped white spot on the inner base, the two middle ones are bordered and tipped with deep red. In this species, the female does not differ very greatly from the male: in her head is of a grey colour, with black spots, and a reddish tint; the streaks are much less conspicuous than in the male; the ash-colour on the throat has a reddish tinge, and is streaked with dusky black; and the whole of the under part is paler in the colour.

In the summer they disappear entirely from the low and cultivated grounds, and are found only in wild and upland places, though there they are inhabitants of the open waters, and not of the wooded districts. They do not quit the low country till March or April, so that it is probable that they have only one brood in the year, whereas those which nestle in richer places have, in general, if not invariably, two.

**THE REED BUNTING (*Emberiza Schœnielus*).** This bird is nearly the size of the mountain sparrow, and is sometimes, though very improperly, called the "reed sparrow." It has been confounded by authors, if not by observers, with another bird, to which it has little or no other resemblance than their both inhabiting the same places. In their structure, their habits, their nests, their eggs, and even in the purpose that takes them to the thickly matted aquatic plants, these birds are entirely different. The one is a genuine warbler, having a melodious and varied, though feeble song; as such it feeds upon insects, resorts to the aquatic plants for them, and does not quit the country till the supply fails. The bird under consideration is a genuine bunting, resident, like the other short-clawed buntings, among tall herbage, of which it eats the seeds, and hence it is found only where graminiferous plants grow; while the warbler, makes merely its dwelling in the herbage, but does not feed on any part of it. It is found among all the tall aquatic plants, though mostly among ridges and reeds, as these form the thickest matting in the shallows and margins of the waters. The bunting is much the larger bird of the two, nearly equal in size to the yellow bunting, and double the weight, at least, of the sedge warbler. The bunting's nest is very seldom placed in the reeds, but mostly near, though it is occasionally at a considerable distance, in a tuft or under a low bush; and when it is among reeds, it is placed where they form a dry tuft or other support, and never suspended to them by a basket-work of leaves, like

that of the warbler. The eggs of the bunting are greyish white, and not quite so numerous; they have a tinge of pale pink in them, and are lined and spotted with chocolate red, like the eggs of the other buntings; and those of the warbler are pale brown, mottled with darker, and without lines. The reed bunting is as destitute of any thing that can be called song as the rest of the bunting genus; and the sound which it utters, such as it is, is delivered in daylight, and while the bird is perching in sight of the observer. The reed warbler on the other hand has a sweet though subdued note, and it sings, in "shadiest covert hid," only at early morn, or in the evening twilight, and sometimes the live-long night.

The appearance of this species may be thus described: length, about five inches and three quarters, of which the tail occupies two and a half; the beak, four lines in length, is black on the upper part, and whitish on the under; the iris is dark brown, the legs rather better than nine lines high, are dark flesh-coloured. The head is black, with reddish spots; a reddish white line extends from the base of the lower mandible quite round the head; it is widest at the cheeks, and narrowest at the upper part of the neck; this part is ash-coloured; the back is black, spotted with white and red, the rump alternately grey and reddish yellow; the throat is black spotted; the rest of the under part of the body is dusky white, with some brown spots scattered over the breast and sides; the small wing-coverts are red, the large black with red edges, in some they are whitish; the pen feathers are dark brown, bordered with pale red; the tail is forked, and of a dusky colour; the two outer feathers have a large wedge-shaped white spot, and the two middle ones yellowish brown borders. The feathers on the head of the male never turn to so good a black after moulting, when in the house, as in the wild state, but are always browner and clouded with reddish white. The head of the female is of a rusty brown, spotted with black; her brown cheeks are encircled with a reddish white streak, which, passing above the eyes, unites with another, which commences at the base of the beak; a dark streak passes down the sides of the throat, which, with the under part of the body, is reddish white, much streaked on the breast with light brown; the colour of the back is lighter, but not so clear as that of the male.

It is probable that buntings, and indeed all birds that feed upon the farinaceous portions of seeds, in the healthy state, are chiefly guided to their food by sight. There is but very little scent in those seeds on which buntings feed, and we do not know much about the sense of smell in birds; most birds appear to us to have the sense of smell very imperfect, and in those which have it very acute, as rooks, carrion crows, magpies, and especially vultures, it is so much more exquisite than any thing of which we have experience in ourselves, that we can say little or nothing about it. The vegetable seed gives no signs of its presence by motion, either in producing sound, or in any other way; and, therefore, sight is the sense that they must depend upon chiefly. With birds that are insectivorous it is different, for most insects and their larvæ smell, and some of them smell very strong: and many of those caterpillars which are quiescent during the day, concealed or sticking out from the branches like little abortive or unproductive twigs, are in active motion during the night. Thus the hours of activity in the two orders of birds vary considerably; and though,

as all of them eat insects, and most of them vegetable matter occasionally, they meet on the confines in a sort of average of the two habits, yet, in the more marked genera of the orders, the times of feeding are almost reversed. In the clear light, during the dry weather, when the seeds are ripening apace, the buntings are all bustle, activity, and clatter, and the warblers are songless in the shade. On the other hand, when night sets in, or when the weather continues wet, and the sky cloudy, the buntings chirp dolefully about the hedges; but the groves and thickets are full of joy and song. The skylark is something intermediate, and is fondest of that weather which first inspired him with song,—showering and shining alternately. The reed-buntings are very energetic in the air, and active in many of their motions, especially those of the tail, which are even more rapid than in the wagtails. The tail is forked at the extremity, and considerably produced and spread. The habit which the bird has of clinging to the flexible culms of the aquatic plants, with free use of its bill, so that it may bruise the husks and pick out the seeds, renders the powerful and ready motion of the tail as a means of balancing, absolutely necessary. The security and even the grace with which it rides, when the stems are laid almost level with the water, now on one side and then on another, are well worthy of notice. It adheres not only as if it were part of the plant, but it contrives to maintain nearly the same horizontal position, with its head to the wind. In action it is the most interesting bird that inhabits the same locality, though not so in song. When the autumnal winds and those of early winter have shaken off the seeds, and the reeds themselves have been borne down by the floods, the reed bunting resorts to other pastures, associating with the yellow bunting and the other graminivorous birds; and in company with them approaching houses and farm-yards, when the weather is severe. With few exceptions, indeed, the resident little birds seek the abodes of man in the winter, and as instinctively come to pick up the crumbs and grains which otherwise would be lost near his habitation, as they resort to other places, and destroy insects and weeds in aid of his cultivation during the summer. In autumn they enter the area or decoy with the chaffinch; in spring, when there is snow, they approach the barns and dunghills, and there, as well as in the open fields, and on the hedges, they are very easily taken with birdlime or a net.

THE SPARROW BUNTING (*E. passerina*). This species must have been confounded by naturalists with the preceding, or it would have certainly been better known, as it is not rare either in spring or autumn. It is a more slender and smaller bird than the former, being only five inches long, of which the tail measures two and a quarter; the bill is light brown below and black above; the iris is of a dark chestnut colour; the feet are three-quarters of an inch in height and dusky flesh-coloured; but the plumage in general is similar to that of the female of the preceding species. The male bird has the top of the head red, with a grey longitudinal streak in the middle, and many black spots arising from the deeper shade of the feathers, which appears in every direction: a dusky reddish white line passes from the nostrils above, and also a little under the eyes, and widening behind on the temples, chestnut-brown breaks through a deep black, which reaches the sides

of the neck, and becomes a spot there; a yellowish white line passes from the under angle of the bill down each side of the neck to the middle, and is lost behind the temples with that which passes by the eyes; the throat is black clouded with pale grey, like the house-sparrow; the rest of the under part of the body is greyish white, speckled on the sides with dark chestnut, but the under tail coverts are pure white; the sides of the neck and upper part are grey-olive, spotted with black, the rump is also the same colour, with a reddish tint; the small wing-coverts are a fine red, the others have only a wide border of that colour, the rest being black. The quill-feathers are blackish, edged with olive-grey, the last with red; the forked tail is black, the two outer feathers have a wedge-shaped white spot, and the two middle ones are edged with red. In the female there does not appear any black on the top of the head, as in the male, and the colours are in general lighter; a reddish white streak passes above the eyes, another descends down the sides of the neck from the base of the beak, a third, but of a dusky black, extends from each side of the chin to beyond the middle of the neck; the throat is a dusky reddish white, the under part of the body the same colour, but continues to become paler to the under part of the tail; the breast and sides are streaked with a red brown; the nape and back of the neck are reddish grey; the back is longitudinally spotted with black and reddish grey. When kept in the house the black disappears from the head of the male, and the upper part of the neck changes to greyish white, spotted lengthwise with dusky black.

The favourite haunts of the sparrow-bunting are in a mountainous country, where there are thick woods and bushes. It is a bird of passage, which comes some time in April and quits us in the latter end of October or beginning of November. Its food is grain of all kinds, and insects, when in the wild state; but in the house it is fed on the same food as the reed bunting; and resembles that bird very much in its habits and song; and may be taken with either the net or birdlime. It is probable that this is only an accidental variety; and the same may be said of the provincial bunting and some others which have been named and described by authors.

**THE CIL BUNTING** (*E. cirrus*). This species is varied in colour above, and yellow beneath, and the two outer tail feathers are marked with a white spot wedge shaped. The cil bunting is six inches and a half in length. Is a native of Italy, France, and the other warm countries of Europe, frequenting newly ploughed fields, feeding on grains, insects, and worms, which last it pulls out of the ground. Though not uncommon in many parts of Cornwall and Devonshire, it was first recognised as appertaining to the British fauna by colonel Montagu, who met with it among flocks of yellow buntings and chaffinches. It generally builds its nest in furze or on some low bush, and is composed of dry stalks, roots, and a little moss, and lined with long hair and fibrous roots. The eggs are four or five in number, cinereous white, with irregular long and short curved lines, frequently terminated with a spot at one end. They pair in April, and begin laying in the early part of May. At a little distance the females might readily be mistaken for the same sex of the yellow bunting, but are obviously different when closely compared. The note of this species is also similar to that of the yellow bunting, but shorter, less shrill, and the final part not

drawn out to such a length. The female has only a gentle plaintive chirp. The principal food of the young bird appears to be insects, especially grasshoppers; and they will likewise eat various seeds, canary being a great favourite. They can be tamed very easily, and will live six or seven years in confinement.

The colours of the cil bunting may be thus described. In the male bird, the bill is bluish above and pale on the under part; the irides are hazel brown; a streak across the eye, and the throat greenish black, with a bright yellow streak above and a paler one below it; gorget pale yellow; the lower part of the breast and sides of the neck pale olive green, with a soft tinge of grey, passing into pale yellow on the belly, and again into mottled tints of reddish or orange on the sides; the centres of the feathers on the head blackish, those on the scapulars reddish orange, passing into blackish brown on the back, and again into reddish brown on the rump; the darker ones margined with grey, the orange with yellowish white, and the red with greyish white; quills greenish grey, with pale yellow margins; the outer feathers of the tail with white webs on the basal half, other feathers blackish, margined with yellowish grey the feet are brown, tinged with red. The top of the head of the female is dull olive green; the chin, where the dusk is in the male, pale brown, with darker streaks; the flanks streaked with brown where they are mottled with reddish orange in the male; the female is rather less, and the colours are in general less pure and bright.

As these birds fly much in company with the yellow buntings in winter, they might be looked for in warmer places, a little farther to the north than they have hitherto been found; though, as they are in a great measure corn-land birds in their habits, the sheep walks on the southern heights may impede their progress to the countries farther to the north, and they cannot be expected on the mountains.

**THE ORTOLAN** (*E. hortulana*). This is a true bunting, and considered as a luxury for the table; it is among the most celebrated of the whole. It is necessary to be somewhat exact in the description of this species (which, by the way, is rare as a British one, and can be considered only as a straggler), because not only the bird-catchers in those countries where it is much in request, but even some naturalists, are apt to confound it with other species. The true ortolan has a wider breast and stronger beak than the yellowhammer; it is six inches and a half in length, of which the tail measures two and a half; the beak, six lines long, is thick at the base, with a bony tubercle at the palate, and is of a yellowish flesh colour; the iris dark brown; the legs, which stand rather more than three quarters of an inch in height, are flesh-coloured; the head and neck is greyish olive; the throat, and a streak on the neck, from the angle of the beak, deep yellow; the back and the feathers of the scapulars chestnut brown, speckled with black; the rump of a dirty grey brown; the under part of the body reddish yellow, waved with light brown; the quill feathers are dark brown, with a red border to some and a grey to others; the tail feathers dark, the two outer ones with a wedge-shaped spot, the others with a red border. The female is rather smaller than the male, of a changeable shining ash-colour on its head, and its neck streaked with fine black lines; its breast, and the upper part of its body,

are lighter coloured. The throat of the young male birds, before they have done moulting, is of a light yellow, with a mixture of grey; the breast and belly are of a reddish yellow, speckled with grey, which make them rather resemble young yellowhammers. A bird-fancier will distinguish the two sexes even in the nest. There are white, yellow, speckled, and in the house sometimes even black varieties.

Though this bird is not found in Great Britain, it occurs in many parts of Europe, as Italy, France, Germany, and even Sweden, migrating in spring and autumn, when great quantities of them are caught, and fattened for the market, being proverbially celebrated for the delicacy of their flavour. That they may more speedily acquire the requisite degree of plumpness, they are shut up in a room, from which the external light is excluded, but in which are placed a few lanterns, to enable them to see to run about, and pick up the millet and oats that are regularly strewed on the floor. Under this regimen they soon get so fat, that they would speedily die if not removed by the dealers. It is pretended that those from the plains of Toulouse are superior to those of Italy. In some districts of the latter country, where they are plentiful, as, for example, in Lombardy, they are not only prepared for the table but trained to sing; and Saserne observes, that there is considerable sweetness in their song. If allowed to associate, especially when young, with other birds, they adopt some of their notes. The female makes her nest in a low hedge, or a vine, or on the ground, especially among corn, composing it carelessly of plants, mixed with leaves and dry or green rushes. She lays four or five greyish eggs, with a very pale tinge of purple, and sprinkled with very small blackish spots. They generally have two broods in the year.

In spring these birds are easily attracted to a decoy bush by a female of their own species, or a yellowhammer. In August a turf place should be chosen near brambles to form a small area as a decoy, like that made for chaffinches. It must be surrounded with a low hedge, with some oat ears fastened to it. About the area should be placed one or several call birds, especially a perching bird, that is to say, a bird of the same species, with a band of soft leather round it, and confined by a small string fastened to a peg-stick in the ground, which prevents its going beyond the limits prescribed. Then it should be given plenty of food and water, in order that the birds to be caught may be the more easily attracted within the area, from seeing one of their own species in a place of abundance. This kind of decoy bird is often more necessary than any other.

The fine form and colours of the ortolan would be quite sufficient to render it desirable, but still more so its melodious flute-like warbling, so clear and full, which has some resemblance to that of the yellowhammer, only that the last notes are much deeper.

THE SNOW BUNTING (*E. nivalis*). This bird is known by many popular names, such as the "snow bunting," "snow flake," and "snow bird," and has been sadly in the way of those who do not combine a little knowledge of the principles of ornithology with the mere observation of individual birds. It has got several trivial names expressive of differences of colour; and it has been specifically called a lark, and also a finch. In reality this is a polar bird, and inhabits the arctic zone in both continents, and though not a mountain-top bird, like our ptarmigan, yet

subject, from the higher latitudes of which it is a native, to greater extremes of seasons than that, it is also subject to similar changes in its plumage. And further, though it does not migrate very far to the southward, it is a wandering bird; it does not change its plumage so regularly or so completely as the flocks that migrate, as the ptarmigan which summer and winter in the same places do, upon the tops of the mountains, even of the comparatively low latitude.

There is something in this well worthy the attention of those who wish to study the adaptation of animals to those circumstances in which they are placed; and if this is not attended to, we name and describe the species, and arrange them into systems, to very little purpose. The mountaineer, whether it be bird or any thing else, does not quit its mountains, or at all events it does not range to a very great distance from them, or wholly quit the country in which they are situated; and this holds true of man as well as of the other animals. It matters not what may be the part of the world, for if we are any where to find the aborigines, we must seek for them in the mountains. In the Pyrennees, the Alps, the Caucasus, and in short every lofty ridge that we can name, we find people who have outlived all the changes on the plains. While too the animals of the low lying places are driven before the weather, the mountaineers keep their ground, and, to enable them to do so, they of course are much more changed, especially in their covering, than animals which, from their migratory habits, are able to endure the milder climates into which they migrate, without those seasonal adaptations.

When the violence of the polar winter sets in, it of course whelms the pastures of these birds completely under snow. They are, however, very irregular in the periods at which they come on in different years, and also in their violence. Of course the snow buntings do not leave their native north until the winter comes, that is, till the snow comes, for the clear black frost often continues for a considerable time before the heavy falls of snow. In consequence of this, the snow buntings appear in the more southerly parts of their range, in very different plumages, according as they come earlier or later, and this seems to be the chief reason why they have got so many names, such as the tawny bunting, the pied finch, the white lark, and several others.

In the summer these birds inhabit the rocks and peat-covered tracks of the extreme north, where they subsist upon the seeds of rushes and other hardy plants; and the produced claws on the hind toes enable them to run on the soft or moss-covered surfaces with more facility than they could do if these appendages were short; but in proportion as this structure fits them for walking upon these surfaces, it disqualifies them for perching upon trees. But there are few or no trees in their native country; and when they migrate to the south, they are ground birds rather than perchers.

When they appear upon our shores, they prefer those places which are most of a polar character; they do not affect the woodlands, neither do they resort to the neighbourhood of houses, or even to the cultivated fields, as is the case with our native birds in the winter. They linger on the cold moors or their margins, and as such places are not very tempting in the season of snow-buntings, it is probable that few are seen in proportion to the numbers which visit

the more inhospitable parts of the country. If, however, these are covered up with snow, the birds are driven to the trodden places; and the snow-bunting, among the rest, comes in for a share of the droppings of horses, which form a chief source of supply to the birds when the ground is covered. The young of early broods are the first to appear; they are more brown in the colour, have the bill yellow, and are smaller in size than the mature birds, and hence they have been described as a separate species.

When very severe snow storms occur at a late period of the winter, the full-grown males sometimes come to Britain in great numbers, and with their winter plumage nearly perfect. They are then pure white, with the exception of a portion of the back, the middle coverts of the wings, and some of the tail feathers and the quills, which remain black. It is in this state that they are called pied finches, or snow flakes. The last of these names is very appropriate; for although most winter birds come before the storm, they are often taken by it on their way, and arrive exhausted amid the driving snow, when many of them perish.

Norway, or at least some part of the country to the north of the Baltic, is probably the country from which they generally come to Britain. Their natural flight is in all probability to the south, and the continent of Europe the place on which they would land if they kept their direction. But as the length of the parallel, and with that the falling behind the rotatory motion of the earth, increases, they are turned to the westward in the very same way that the storm is; and thus though the unequal motion both of snow flakes and of snow is from the north, they really come from the north-east, the motion of the storm giving additional obliquity to that of the birds.

The best account of their appearance in Germany (they do not reach the more southerly parts of the continent), is that given by Bechstein. "When the winter is severe," says he, "these birds are seen from December to May, in many parts of Germany, where they even approach the villages. I am persuaded that, if attention were paid to them, they might be seen in every direction during March, on their passage to the north; whilst the snow is on the ground they are found in company with larks, on the high roads and in the fields, they may then be taken with horse-dung placed in a net, or covered with birdlime, or by clearing a spot of ground of snow, and strewing it with oats. I have had a pair in my room six years without a cage, and they are satisfied with food common for other birds; if kept in a cage, they must be fed on hemp-seed, oats, millet, rape, and poppy seeds. They appear much delighted whilst bathing: during the night they seem very uneasy, hopping and running about continually. Their strong and piercing cry resembles a loud whistle; their song would be rather agreeable were it not interrupted in a peculiar manner; it is a warbling mingled with some high noisy notes, descending slowly from shrill to deep, and a little strong and broken whistling. Heat is so contrary to their nature, that they cannot be preserved unless carefully guarded from it.

As the winter sets in, large flocks of these birds proceed from the north of the Baltic and distribute themselves over the low country in Poland; but in that longitude their migration extends not further than the Carpathian mountains; and they begin to disappear on their return to the north in February

and March. On the American continent they do not advance farther to the south than the state of Virginia. The numbers of them that assemble in the north during the summer season are immense, so much so, as to give a character even to the remotest countries which have been visited. Countless thousands are found on the ice near Spitzbergen: and there are numbers also in Greenland. They breed in the fissures of the rocks. As already hinted, numbers of them frequent the north of Scotland, and some of them are even understood to breed there; and in the Orkney islands they are especially numerous. They are not unknown in England, though we believe they seldom come further to the south than Yorkshire. After their long flights, they are usually much exhausted, but they soon recover and get very fat; in which condition they are styled ortolans of the north. They are inferior in size, and perhaps also in flavour to the genuine ortolans of the south; but still, from their numbers, as well as their quality, they form a valuable addition to the food of the northern people. Their appearance in the British islands is supposed to betoken a severe winter, or heavy falls of snow. These birds do not perch, but continue on the ground, and run about like larks, which they also resemble in size, and in the length of their hind claws, and by some authors they have been accordingly ranged with that family; but, from the peculiar structure of their bill, they are now, with more propriety, referred to the tribe of buntings. They sleep little during the night and are very wakeful, and, in the months of June and July, begin to hop about with the earliest dawn. The male sings feebly during the breeding season; his call note is more agreeable, but that of alarm or anxiety is, on the contrary, loud and shrill. He sings from the beginning of May till the end of July, and often during the night, which they always pass on the ground. The female builds in the crevices of rocks, constructing a nest of grass and feathers, lined with the hair and wool of the arctic fox, or other quadruped, and laying five or six reddish white eggs, spotted with brown, and nearly spherical. The male assists in the duty of incubation.

Snow-flake.

The snow bunting is nearly of the same size as the lark, six inches and a half in length, of which the tail measures two inches and two thirds. The beak is half an inch in length, with every characteristic of the bunting species, of a conical form, rather bent at the sides, and having a bony tubercle like a grain of barley at the palate; its colour in the singing season is entirely black, at other times the point alone is black, the

rest yellow. The legs, which stand an inch high, are black. The neck and all the under part of the body are white, and the head is white spotted with brown. The back and rump are black, with pale margins to the feathers. The quills are white for half their length from their base, and black in the one web for the rest of their length. The tail is forked with three of the lateral feathers on each side white, with a black spot on the tip, and the next four black with a yellow border. The female is smaller and browner in the colour. The male, in the breeding season gets considerably blacker than is stated in the above description; and, indeed, there are few birds of whose colours it is more difficult to give an account that will apply to all the individuals, or even to one individual at all seasons.

THE LARK-HEELED BUNTING (*E. calcarata*). This species is named from the great length of the claws on the hind toes, which are nearly as much produced in proportion as those on the lark. It is about the same size as the former, or perhaps a very little larger; and it is an inhabitant of the same countries, but of places more inland and mountainous, so that it is less of an emigrant. On the continent it goes occasionally more southward during very severe weather, and we believe it has been observed in Britain, but only as an occasionally rare straggler. Its habits are very little known. The general colour on the upper part is fawn spotted with black; and the throat and upper part of the breast are black in the male during the breeding season; but in winter the black breaks into streaks, something similar to those in the female, but darker and better defined.

Very many birds besides those which we have enumerated, have been described by various authors as buntings, and of these not a few are more allied to the linnets. They are in general inhabitants of the warmer parts of the world, and too little is known of their habits in a state of nature for enabling us to class them with anything like accuracy.

EMBLICA (Gærtner). A genus of shrubs, natives of the East Indies. Linnæan class and order *Monœcia Monadelphica*, and natural order *Euphorbiaceæ*. Generic character: flowers monœcious; calyx six-cleft; stamen, filaments single, filiform, long, trifid at top; anthers attached by the back and with the filaments forming a point; styles three, united at the base, split at the apex into several recurved divisions; capsule drupaceous, three berried, each two-seeded. This is the *Phyllanthus emblica* of Linnæus, and the *Nymphanthus* of Lourino.

EMBOTHRIUM (Forster). An ornamental shrub found in New Holland, belonging to the natural order *Proteaceæ*.

EMERALD. This precious stone has long held a high place for its colour and brilliancy, and there are few mineralogical cabinets that are without specimens from Peru and Brazil. The emerald and beryl have a strong resemblance to each other: this both are green, their crystallisations differ but little, and in point of fracture, hardness, and weight, they are nearly the same. Notwithstanding these agreements, they are readily distinguished from each other by the following characters. The emerald occurs only of a green colour, but beryl, besides green, is also yellow and blue; the crystals of beryl are long, those of the emerald are short; the lateral planes of the beryl are streaked, those of the emerald are almost always

smooth; the terminal planes of beryl are smooth, those of the emerald are rough; and beryl is rather softer than the emerald.

Many of the emeralds described by the ancients appear to have been varieties of green fluor spar. Even in more modern times, green fluor spar has been preserved for emerald. Mr. Coxe examined the celebrated emerald table in the abbey of Reichenau, near Constance, which he found to be a very fine green-coloured fluor spar. The celebrated *sacro cattino di emeraldo orientale*, preserved at Genoa, is in reality but a mass of cellular glass. Many of the fine Ethiopian emeralds, which were bequeathed to monasteries, appear to have been sold by the monks, and coloured glass substituted in their place.

This mineral was named *smaragdus* by the ancients. Pliny distinguished twelve species of the *smaragdus*; but under this title he includes, besides the true emerald, also green jasper, malachite, fluor spar, serpentine, and some varieties of gypsum. Theophrastus also mentions the true emerald, which he says occurs in small quantity, and very rarely: he enumerates along with it another mineral of a green colour, which he informs us is found in masses ten feet long, and is probably a variety of serpentine. The emerald with which the hall of Ahasuerus was paved; the pillars of emerald in the temple of Hercules, at Tyre, mentioned by Herodotus; and the large emeralds described by Pliny as having been cut into columns and statues, cannot be referred to the true emerald. Indeed the confusion that prevails in the descriptions of this mineral in ancient authors, has led some mineralogists to believe that the true emerald was not known till after the conquest of Mexico and Peru by the Spaniards. The primitive form of the rhomboidal emerald is an equi-angular six-sided figure, and the prismatic emerald has a strong double refractive power.

EMEU. A very singular bird of New Holland, classed by Cuvier in his order *Echassiers*, or stilt birds, and in the division *Brevipennes*, or those which have no feathers fit for flight, but perform all their progressive motions on foot upon the ground. If *Brevipennes* is to be retained as the name of the division, and as it is founded upon the most remarkable external character of the animals, there can be no other objection to it, than that it would require to be divided into two families, *Struthionides*, or fast running birds, and another to include the apteryx, and the dodo, if they ever should be found in the live state.

There are four distinct races of the swift running birds, the ostrich of Africa, the rhea of South America, the cassowary of South Eastern Asia, and the emeu of New Holland, the bird more immediately under consideration. Each of these has characters sufficiently distinct for entitling it to rank as a separate genus, though no generic name that is quite unobjectionable has yet been given to the emeu.

The emeu is a very large bird, bearing some resemblance to the cassowary of Asia, and has been in consequence often called by the same generic name. It wants, however, the horny plate, or helmet, which characterises the other, and there are besides many differences between them. Perhaps the other bird of the family which it resembles the most is the African ostrich, but still there are many points of dissimilarity. Its body is more clumsy than that of the ostrich, its neck is rather shorter, its legs are also shorter, and, perhaps, stouter, and its feet have three toes, all directed

to the front, while those of the ostrich have only two. The claws, also, have something of the form of those of the *rasorial*, or scraping birds, while those of the ostrich have more the appearance of nails. The feathers on the emeu are all of a loose and flocculent texture, intermediate in appearance between the feathers of flying birds and loose and silky hair, matted into small locks, but none of them have that graceful form which is so much admired in the produced feathers of the ostrich. The feathers are of a dull sooty brown colour, with some markings of obscure grey, which appear as if the darker colour had been worn off. The head and neck are small in proportion to the size of the bird, and are nearly destitute of feathers. The wings are very short, of the same sooty colour as the back, and the only feathers which they contain are loose and hairy down over the sides. They act as balancers when the bird runs, but they are totally useless for flight. The bill is of mean length, straight, and ridged on the culmen, but does not advance in the form of a plate on the forehead. The young are streaked with brown and dull white, and they retain for a considerable time a portion of the down with which they are covered when they leave the shell, intermixed with the young plumage. The sides of the head are thick with this down after the birds have attained considerable size. They have sometimes been figured in this state as the mature birds, and thus led to the forming of very false notions of them. In their mature plumage, the two sexes differ little from each other in colour.

The food of the emeu consists of vegetable substances, such as grass, buds, berries, and roots; and from the structure of its toes and claws it is probable that it may occasionally scrape the ground in search of the last. It is, however, a very shy and timid animal in its native haunts, the wilds of Australia; and it is so very swift footed, that very little is known of it in a state of nature, farther than can be observed when it is hunted. Of course it nestles on the ground, although most probable in the extended copes, or "bush" as they are called in that country, as these are the places in which it seeks safety when hunted by dogs, and if it can reach them it is in general safe. The eggs are about five or six in a batch, nearly the same size and shape of those of the ostrich, but of a sea-green colour. They are edible, and one reason why the number of the birds is but small as compared with the extent of their pasture, is the assiduity with which the eggs are sought after by the "bush-rangers," or runaway convicts, and the more lynx-eyed aboriginal inhabitants. It does not appear that these birds form any very regular nest, or, indeed, a nest of any kind, and the formation of nests is not a general practice with ground birds, few of the gallinaceous birds giving themselves that trouble. What may be the physiological cause is not known, but the physical fact is certain, that birds are careful in the formation of their nests in proportion as they are air birds, and depend upon the wing for the finding of their subsistence. It should seem from this that, as we have had occasion to remark in some previous articles of this work, the production of feathers fit for rapid or continuous flight, is the operation which in the feathered tribes requires the greatest care. We find evidences of this curious fact throughout the whole class of birds, as they all have a nest carefully prepared, and remain longer in it, in proportion as they are more decidedly birds of flight; and even

among the ground birds which do not, as we have said, form elaborate nests in any instance, we have a gradation in the rude and rudimental place for the hatching. The ostrich may be regarded as the most completely wingless of birds with whose manners we are acquainted, and the ostrich deposits her eggs upon the bare sand, though she does not abandon them then, especially when the cold nights and the dew (for there is dew even on Sahara) set in, as is stated in the vulgar accounts of the bird. The emeu is not an inhabitant of quite such barren places as the ostrich, and she therefore, we believe, generally, if not invariably, drops her eggs in the bush, and both male and female sit upon them. There have been some peculiarities noticed of the emeu in a state of domestication, of which we shall have to take some notice afterwards, but no inference can be drawn from them as to the conduct of the birds in a state of free nature.

In their native haunts among the plains and brushes of Australia, the emeus have, since the colonisation of the country by Europeans, had two sets of enemies to contend with, besides the native dogs, which of course have been enemies to them under all circumstances.

In the open plains, it is not very easy for the colonists to come so near the emeus as to make them gun sport, and lying in wait in the bush is not a very noble sport. Thus they, in general, prefer (we believe) coursing the birds with swift dogs. The dog must be very swift in order to come up with the emeu, and the coming up with the herd is rather more ticklish than that with animals which are are coursed in European sport. The emeu kicks with vast force; and the size and vigour of the foot are such that, if the stroke were to take effect, it would fracture the skull of the strongest dog, and lay him dead on the ground in an instant; the dog thus requires to be trained in a peculiar manner. He must not make his approach directly in the rear of the bird, as in that case, the stroke of the foot would take effect, and the triumph of the bird would be final. He must come to the side and seize the body of the prey, in which case he is safe, and the emeu is subdued at once. But even when the dog is so trained, the bird has the better of him in the first part of the chase, and it is only when the run is so long that it loses wind, that it can be taken by the dog, be his racing what it may.

This is a curious fact in the different economy of birds and mammalia. As a denizen of the air, a bird is lungs all over, and does not appear to lose wind under any circumstances; the fact of its falling a prey to another bird in the air, appearing rather to be the failure, or the inferiority of muscular exertion. But on the ground, which is the proper arena of the mammalia as a class, and not that of the birds, it seems from this case of the emeu, that the bird fails from laboriousness of breathing. This is a very curious subject, but we have no room, neither is the present the place for entering into any explanation of it.—In all probability it would not be very easily explained, until some farther observation and investigation have been made. Indeed the peculiar circumstances which adapt classes of animals to their elements, have been too little attended to by writers on natural history.

As the European settler, with his hound, is the enemy of the emeu upon the open plain, so the native Australian, with his spear, is its enemy in the bush. There he lies in wait; and as, by being practised from

the earliest time that the hand has any power of action, the aim of the spear is very certain, the bird seldom escapes from it if it comes within spear range of the lurking savage.

Between these enemies the numbers of the birds are very much reduced, and it does not appear that any attempts are made to increase their numbers by domestication in the colony, though they are very easily domesticated. As food, they are not indeed so palatable as many birds of smaller growth. As they are running birds, with no power of wing, the whole of the growth is concentrated upon the posterior part of the body; and, with the exception of the thighs, there is no part of them that contains any muscle worth eating. When the bird is in good condition, a great quantity of soft fat accumulates upon the rump, and all the hinder part of the body. This fat is of the same rank description as the fat of a goose, or even more so, and does not increase the value of the bird as an article of food, at least to persons of any delicacy of taste. As is the case with the accumulated fat of almost all birds, it consists wholly or chiefly of *elaine*, or oily fat, without any admixture of *stearine*, or crystallisable matter, so that if it were cooked with the flesh of the bird, it would be so rancid as not only to be not edible itself, but to spoil the rest. It is, therefore, removed before the part of the bird which is made use of as food is cooked; and the quantity is so considerable, that the emeu is often hunted for the sake of its oil, by those who care nothing for the flesh. When the flesh is an object, it is only that on the thighs which is so, for on the rest of the body it is so small in quantity, as not to be worth taking off the bones. Even on the thighs it has none of the delicacy of the flesh of ordinary birds, but rather resembles beef; and in the old birds it is exceedingly tough, though in the young ones it is more tender, and far from being unpalatable. The flavour of the legs, or rather the thighs of these birds, being that of beef rather than of fowl, is not an uninteresting point in physiology, the more so that there is an approximation to the same thing in other birds. The less that any bird, in the general character of its class in wild nature, is dependent on the wing, and the more that it is dependent on the foot in its economy, the more does its flesh resemble that of the mammalia. Thus in a common fowl, the legs are darker in the colour, and have more the flavour of beef than the wings, or than the muscles on the breast, by which the wings are put in motion. It should seem that the aerial muscle is in all cases less loaded with blood than the ground one; for the darker hue and the peculiar flavour may be, in great part, attributed to the quantity of that fluid contained in the capillary vessels; and if the ground part of the bird is not hardened by too violent exercise, it is probable that those dark portions that have a relation to walking, would be much more racy and nutritious than the paler ones which are connected with the organs of flight. In capons, which have little exercise, the legs are the best parts, and even in common fowls, though they are perhaps not the most in esteem, they are certainly the most juicy and the most wholesome. Nor is there any doubt that in the using of birds as food, every bird is more wholesome in proportion as it is more a ground bird.

These facts are worthy of some attention, with reference to the emeu. It is a very hardy bird, bearing the climate of Britain very well, and if attended to, would, in all probability, be much more

easily reared than some others of the birds which are bred for domestic use—than the turkey for instance. Besides, emeus are by no means chary in their feeding. The pastures of New Holland, though extensive, are any thing but rich, the grasses are scarce, the berries are harsh, and few of the roots contain much farinaceous matter; so that, in a state of nature, the emeu may be said to live upon the very coarsest food—food far inferior to that of any sort of poultry in this country—so that it might, in all probability, be introduced with advantage as an economical bird.

Though timid and shy in a state of nature, it is tamed with the greatest ease; and when tamed, it is exceedingly gentle. Those which the Duke of Devonshire had at Chiswick, notwithstanding their great size, never showed any symptom of pugnacity, but were mild, and even playful. In the cold weather they amused themselves by dancing; and in no case did they attempt to make an attack upon any other creature.

It should seem, therefore, that the emeu is a bird which could be introduced into the farm-yards in this country with great ease, and with no inconsiderable advantage. Nor is there any doubt that if it were subjected to no more exercise than were necessary for the preservation of its health, the flesh would become much more tender, and the bird really be valuable in an economical point of view. But, in these matters, as in all others, the mere economy of pounds, shillings, and pence is not the only economy, any more than mere eating and drinking are the only enjoyments of human life. It is desirable that the farmyard should be a study of information, and a source of intellectual pleasure, as well as a means of profit; and for this reason the more animals that can be introduced into it, the better must it be for all parties.

Emeu.

Hitherto emeus have been introduced into this country only as objects of curiosity, without any reference to economical purposes, or even to the means by which their numbers might be most certainly and successfully multiplied. That they will breed in the open air in our climate, is proved by the fact of their actually so breeding at the farm which the Zoological Society of London had between Rich-

mond-park and Kingston. Their conduct there shows that the male takes more interest in the rearing of the young than is done by any of our common domestic poultry; and from the attention which he shows in this respect, there is reason to believe they are monogamous. While a pair of these birds were kept in a pen at the place mentioned, the female, in the early part of the summer, dropped at different times nine eggs. She made no previous nest, nor did she appear to take any care about dropping the eggs in the same place. But they were no sooner dropped than the male bird took charge of them. As they were dropped he rolled them gently along with his bill, collecting them together; and set about performing the labour of incubation. This he continued to do with the greatest assiduity for the period of nine weeks. The result of this paternal incubation was the production of five young emeus. These birds are now so well-known in this country, that farther description is not necessary.

**EMMET.** A little insect, sometimes also called a pismire. These two names were employed by our earlier authors for the ant.

**EMPETREÆ**—the Crowberry family. A natural order of monochlamydeous dicotyledonous plants containing three or four genera, and a similar number of known species. This order appears to hold an intermediate place between *Euphorbiacæ* and *Celastrineæ*, to the former of which it bears a strong affinity. It is at once distinguished by its inferior distinct imbricated sepals, its definite ascending ovules, its distinct stamens, and its want of petals.

Its essential botanical characters are: flowers dioecious; sepals consisting of many hypogynous imbricated scales; stamens equal in number to the sepals, and alternate with them; filaments long; anthers roundish, two-celled, the cells distinct, bursting longitudinally; ovary free, situated on a small fleshy disk, three, six, or nine celled; ovules solitary, ascending; one style; stigma radiating, the number of its rays corresponding with the cells of the ovary; fruit fleshy, surrounded by the persisting calyx, three to nine-celled, the coating of the cells bony; seeds solitary, ascending; embryo cylindrical, in the axis of a fleshy somewhat horny albumen; radicle inferior.

The plants belonging to this order are small heath-like shrubs, with evergreen, alternate or whorled, exstipulate leaves, and minute axillary flowers. They are found in Europe, North America, and the Straits of Magellan. Many of them possess acid properties. The chief genera are, *Empetrum*, *Corema*, and *Ceratiola*.

*Empetrum nigrum*, black crowberry, or craneberry is abundant on mountainous heaths in the north of Britain. It is a small branching shrub bearing black clustered berries, which afford abundant food to the moor game. The plant endures cold well. Its berries are eaten by the Highlanders, but they are by no means a desirable fruit, and if taken in large quantities are said to occasion headache. Although watery and insipid, they sometimes prove very acceptable to the traveller on the mountains. They are used as food by the Russian peasants, and in Kamtschatka are boiled with fish. They are said to possess anti-scorbutic and diuretic properties. When boiled in alum they yield a dark purple dye. The crowberry is the badge of the clan Maclean, in Scotland.

**EMPIDÆ.** A family of dipterous insects, belonging to the section *Tanystoma* of Latreille, nearly al-

lied to the *Asilidæ* (see **BOMBYLIIDÆ**), from which they differ in their smaller size, less robust structure, and in having the proboscis long and perpendicular. The head is nearly globular, and the eyes very large. These flies are of small size; they are very numerous in respect to their species as well as to the number of individuals. Some of the species may be noticed in the summer flying in great numbers, and with great velocity, over standing waters close to the surface, over which they rush as though impelled by the wind; others are found in trees and upon plants, where they prey with avidity upon other insects, and so greedy are they that we have noticed them thus occupied even during coupling. There are numerous generic and sub-generic divisions, resting merely on minute structural differences.

In the typical genus, *Empis*, the proboscis is much longer than the head, the terminal style of the antennæ biarticulate and short. The type of the genus is the *Empis borealis* of Linnæus, a species found in Ireland, having the wings broad and black, and the hind legs in the females plumed.

**EMPLEURUM** (*Hortus Kewensis*). A small, ornamental evergreen shrub, native of the Cape of Good Hope. The flowers are monœcious, and rank in the order *Diosmeæ*. It is a greenhouse plant of easy culture.

**ENCELIA** (Cavanille). A genus of two evergreen shrubs, natives of South America, belonging to the natural order *Compositæ*. The flowers are orange or yellow, grow well in any light soil, and require ordinary greenhouse treatment.

**ENCEPHALUS** (Kirby). A genus of minute coleopterous insects, belonging to the section *Penlamera*, family *Staphylinidæ*, and subfamily *Aleocharidæ*, having the head small and inflexed, the thorax very short and broad, the abdomen short and very broad, flat above, with the margins elevated and notched, the antennæ thickened at the tips, and the palpi with the last joint slender. The peculiar form of the various portions of the body above described enables the little creature, constituting the type of this genus, to accomplish a mode of defence against its enemies, which, from its singularity, will not fail to interest the observer of nature. Amongst the various means by which insects are enabled to defend themselves when attacked, the instantaneous imitation of death is one of the most efficacious; this is effected by different insects in different manners. In some cases, as in the *Ptinidæ*, the limbs are simply laid along the breast and held there in a state of rigidity until the danger is over; in others, as in the mimic beetles (*Histeridæ*) and pill beetles (*Byrrhidæ*), these limbs are suddenly folded up and received into cavities prepared on the under side of the body for this express purpose; others again roll themselves into a ball, by bending the head and posterior extremity of the body beneath the breast, whereby the legs are covered, and the insect appears like a morsel of stone or a seed. This is the mode adopted by the genera *Agathidium*, *Leiodes*, and *Clanibus*, in the coleopterous order; and by the beautiful *Chrysididæ* in the hymenopterous order. This manœuvre however, as we have shown in our article upon the latter family, does not always succeed, the insect mimic escaping, it is true, with its life, but suffering the loss of its wings. But a more common and repeatedly observed instance of the adoption of this kind of defence is found in the common wood louse (*Armadillo vulgaris*), which, when disturbed,

rolls itself into a globular mass, so completely destitute of all appearance of life, or even of animalism, that it looks rather like a striped bead, and indeed by ignorant persons it may be, and in fact has been, mistaken for one of these ornaments. Swammerdam relates an instance in which one of his maid servants, having found a number of these insects rolled up, began to string them with a needle and thread, but, as may be easily conceived, the insects very soon gave unequivocal signs of life, "being obliged," as Swammerdam says, "to throw off the mask and resume their motions; on seeing which the maid servant was so greatly astonished that she threw away the woodlice and the thread, and cried out and ran away." The encephalus has a different mode of effecting the same object. Instead of bending the abdomen beneath the breast, as in the instances above mentioned, we find it turned upwards and thrown over the back, its flat upper surface laying close upon the elytra, the toothed edges of the former forming a kind of overhanging edge to a convex roof composed of the under-side of the abdomen; the head, moreover, is applied close to the breast, so that the insect now resembles a small round pebble of a shining black colour. In the ordinary species of the *Brachelytra* (see the figure of the Devil's coachhorse in the article upon that group) the abdomen is occasionally turned upwards, but in the insect in question this power is carried to its greatest extent, and applied, as we have seen, to a purpose different from that for which the attitude figured is employed, namely, the discharging of a caustic or pungent smelling fluid or vapour from the extremity of the uplifted abdomen.

The type of the genus, *E. complicans*, is about one-sixth of an inch long, and is found in the winter in moss, and in damp situations.

ENCHANTER'S NIGHTSHADE is the *Circœa lutetiana* of Linnæus, a common weed, growing in damp shady places. It has been observed by a late writer that, although this plant has been named after the famous mythological enchantress Circe, it is entirely innocuous, possessing neither deleterious, or useful properties of any kind.

ENCYRTUS (Dalmann). A genus of minute hymenopterous insects, belonging to the section *Pupivora* and family *Chalcididae*, distinguished by having the deflexed nerve of the upper wing attached to the costal nerve at the extremity of the latter, and by having the intermediate tibiae and tarsi dilated. These insects are of very small size, but interesting on account of their peculiar construction, and of their economy, being parasitic upon various species of scale insects (*Coccidae*), which they destroy in considerable numbers; whence they may be regarded as very serviceable aids to the gardener and horticulturist. The antennæ are subject to various remarkable modifications of form in the different species, of which there are a very great number, and the colours of the sexes are likewise very varied. In their motions they are extremely active; indeed, from the quickness with which they leap to a great distance, they are difficult to be captured. One of the species, *E. vitis*, attacks the vine, fretter (*Coccus vitis*). The male is black and the female red. It is figured in Mr. Curtis's British Entomology.

ENDIVE is the *Chicorium endivia* of Linnæus, a well known salad and culinary vegetable, belonging to the order *Compositæ*, and giving a title to one of the sub-orders of that extensive natural order.

There are five species of this genus, one, the *C. intybus*, is British, and commonly met with by road sides and banks of hedges. In Germany it is cultivated for its roots, which, when cleaned and dried, are ground to powder, and used as a substitute for coffee. Three species are weeds, and the remaining one is our present subject.

This being a winter salad plant, it is needless to sow it before the first of June; if sown earlier it soon runs to seed. The second and third sowings should be made in the first and third weeks of July, and two other sowings may be put in during August.

The seed may be either sowed on seed beds, to be transplanted, or in drills where it is intended to stand for good. Although endive may be successfully transplanted, it does better to remain where it is sown. In fact, there cannot be a better way than sowing a double number of drills on the same seed bed, every alternate one to remain, and the intermediate ones to be transplanted.

The transplanting season continues from the end of June to the first week in October, and at this last mentioned period the plants should be placed in frames, under glass, for protection against the severity of winter. Whenever or wherever planted, it should have full room to spread; and if in its favourite soil, a rich light loam, fourteen inches between plant and plant will not be found too much. When transplanted into drills at this or any greater distance, the plants should be dibbed into shallow furrows made by the hoe; not only because it gives the roots a deeper hold of the ground, but very much facilitates the application of water, and which, if the season be dry, will be required not only when first planted, but occasionally afterwards, to induce a rapid growth.

As endive is never used until blanched, it is, as soon as full or pretty well grown, tied or earthed up for this purpose. There are various methods practised for accomplishing this object; gathering up the leaves all round into a compact bundle, and binding them in that state with strings of matting, is one of the easiest methods; or, instead of ties, drawing earth round each plant while so held up, answers the same purpose. Some blanch their endive by laying plain tiles on each plant, or by a long board laid along the rows. But it must be observed that in all cases the leaves must be perfectly dry when tied up or covered to prevent rotting, which would certainly happen were they tied up wet. In ten days the plants thus treated will be sufficiently blanched for use; so that to keep up a supply, a certain quantity, according to the consumption, should be consecutively tied up or otherwise blanched. By thus depriving the central leaves of the plant of light and free air, the bitter quality is corrected, and the crisp delicacy improved; besides, extreme whiteness is a great recommendation at table. Being one of the principal winter salad plants, it deserves every attention in order to have full-sized perfect plants in that season. Those sown at the end of July and during August are most to be depended upon for winter use. The soil can hardly be too rich for endive, and when allowed ample space it arrives at a fine bulk for salads for kitchen use before the winter sets in. When frost threatens, however, the plants must be removed to a place of safety. This is usually done by tying up all the largest plants on a dry day, and raising the roots out of the ground with good balls of earth, and replanting close together among dry sand, in a pit or frame that can be covered

by glass and mats in severe weather. Or if laid in a sloping bank of dry sand, in a shed or dry cellar, the endive thus protected will keep good for a considerable time. That planted in frames in October and covered with glass, or such as has been planted on dry borders to be occasionally covered with straw, comes in for spring use, and lasts till succeeded by lettuce.

The different varieties of this plant cultivated in Britain are, the green curled, white curled, green broad-leaved, and white and new Batavian. The two first are preferred for their elegant appearance at table, and the last are mostly used for stewing, but are excellent and wholesome salad herbs.

**ENDROMIS** (Ochsenheimer). A genus of handsome moths (*Lepidoptera Nocturna*), belonging to the family *Bombycidae*, and to the section having the wings entire, and forming a triangle in repose. The body is short and thick, the wings somewhat pellucid, the palpi scarcely visible, and the antennæ in both sexes bipectinated. The type of the genus is the beautiful and rare moth known by collectors under the name of the Glory of Kent, *Bombyx versicolor*, Linnaeus, which is of a rich brown colour, variegated with black streaks, and paler markings. The female is larger than the male, and of a paler colour. It is found very early in the year. We have seen the males flying with great velocity in the afternoon towards the end of March, in Coombe-wood, Surrey, in search of their sluggish females, which, from wanting the spiral spring and socket at the base of the upper wings, are unable to effect such a powerful flight. Mr. Haworth was of opinion that the males of this species "assembled," as the gathering together of many of this sex in search of an individual of the other, is termed by aurelians; but from the continued rarity of the species in our cabinets, this can scarcely be the fact.

**ENGIDÆ** (MacLeay). A family of coleopterous insects, belonging to the section *Pentamera* and sub-section *Necrophaga*, or those species which feed upon dead animals and vegetable matters. The *Engidæ* seem to be more attached to the latter, since it is in putrid fungi, and in the neighbourhood of decaying trees, that they are more generally found. Many of the species are of a flattened form, with the body highly polished, enabling them to make their way with facility under the bark of trees; indeed, some of the species were arranged by Latreille amongst his *Xylophaga*, although the tarsi do not agree with the general structure of the true *Tetramera*, amongst which they were placed. It is true that many of them are not decidedly pentamerous, but their general appearance and their habits bespeak their affinity with the more typical species, such as *Engis*, *Ips*, &c., rather than with the *longicornes* or weevils. Indeed, these insects appear to be exceptions to the system founded upon the number of joints in the tarsi, rather than proofs of its incorrectness. The body is more elongate than in the *Silphidæ* and *Nitidulidæ*, and the antennæ are short and terminated by a club, composed of two or three joints.

It is difficult, in our present ignorance of the larvæ of many of the genera of which this family is provisionally composed, to assign exact limits to it, or to give other than very general characters. The lower jaws are generally elongate, and terminated by a strong brush of hairs; the palpi are short, and either filiform or but slightly clavate, and the legs are short

and slender. Mr. Stephens adds—"The family evidently requires sub-division, although in habit and economy, so far as known, there is great similarity, which, probably, only arises from the juxtaposition of the genera of which it is at present composed; the species usually subsist on decaying vegetable matter, either on fungi, agarics, the putrid sap of decaying trees, or upon flowers: they are found at the roots of grass, beneath bark, in fungi, and but rarely if ever, in putrid animal substances."—Illustr. Brit. Ent. iii. p. 57.

The species are generally of small size, indeed some of them are amongst the most minute of the insect tribes; the *Atomaria minutissima* being scarcely one-hundredth part of an inch in length. The principal genera are *Cryptophagus*, *Atomaria*, *Engis*, *Ips*, *Nemosoma*, *Cerylon*, and *Latridius*, to which *Syleuanus* and *Mycetophagus* may be provisionally added.

The typical genus *Engis* has the body oblong, oval and convex, the antennæ short, thick, with a three-jointed club; the legs are short and stout, and the tarsi five-jointed. There are several British species, the type being the *Dermestes scanicus*, Linnaeus, a species about one-sixth of an inch long, found in boleti, &c. Some of the exotic species are of a much larger size, and must be of infinite service in clearing away the putrifying masses of vegetation which abound in tropical climates.

**ENKIANTHUS** (Loureiro). A genus of beautiful and highly ornamental Chinese plants, belonging to the tenth class of Linnaeus, and to the natural order *Ericææ*. Generic character: calyx bracteate, five-cleft, persisting; corolla bell-shaped and slightly five-cleft, with five nectariferous cells in the bottom; stamens inserted into the base of the corolla; filaments pilose and dilated at the base; anthers two horned, having double pores which open at the apex; style filiform and persisting. Drawings and specimens of the *E. quinqueflora* were first brought to England, under the name of *Andromeda arborea*, in 1794, as no small plants were purchasable at Canton in the previous year, but living plants were received in this country in 1812. No plant is more regarded by the Chinese as a domestic ornament than this when in flower. Small branches of it are sold in the streets of Canton about the first of March, and nearly for the same purpose as holly and mistletoe are sold in London before Christmas, viz., for decorating places of worship, and for placing before the images of Joss in their houses. The branches are cut from the trees just before the flower-buds are expanded, and placed in vessels of water, where they bloom beautifully. The flower-buds being terminal, and each containing four, five, or six flowers of a delicate pink colour, hang gracefully from the point of every spray. As the leaves are not produced in water, and as the spray is arranged very neatly in the vessels, they are aggregately a beautiful object. Every street window is more or less decorated with these flowers in the season, and which shows that there must be vast numbers of the trees in the vicinity of the city, and yet not one small plant could be found in the nurseries in the spring of the year 1794, though twenty dollars were offered for a potted plant. Another species, the *E. reticulata*, was added to our collections in 1822; and as they are nearly deciduous trees, hopes may be entertained that they may be in time injured to our climate. They are propagated by cuttings.

**ENTADA** (Adanson). A genus of plants found both

in the East and West Indies, belonging to *Polygamia Montecia*, and to the natural order *Leguminosæ*. Generic character; flowers polygamous; calyx bell-shaped, five-toothed; petals small and oblong; stamens ten or more, elongated; anthers roundish; pod very large, compressed, jointed; valves often separated in two by a membrane. These are climbing plants, and have been called mimosas by several botanists; and by Forster, one of them was called *Adenantha*. They are treated as stove plants and propagated by cuttings. The chief peculiarity of these plants is the immense size of the pods, those of one variety are six or eight feet long, and, being gently curved, resemble gigantic cimeters. Their seeds are nearly six inches in circumference.

**ENTALIUM** (De France). A fossil species of shell, of the genus *Dentalium*. It includes such species as have the tube narrowed near its orifice, with an interior tube throughout its length. The *Dentalium duplicatum* illustrates this genus.

**ENTELEA** (R. Brown). A deciduous tree, native of New Zealand, introduced in 1820. It belongs to the natural order *Tiliaceæ*; is treated as a greenhouse plant, where it flowers, and occasionally ripens seeds, by which it is propagated as well as by cuttings.

**ENTOMOLOGY**. That portion of zoological science, which treats of the insect tribes, as restricted by the knowledge obtained by the elaborate researches of modern comparative anatomists. The term is derived from two Greek words, *entomon*, an insect, and *logos*, a discourse; the former word, as well as the synonymous Latin word, *insectum*, which we have Anglicised into insect, being themselves compounded of other words, signifying a cutting or dividing into sections or articulations, whence, in fact, we arrive at one of the great characteristics of these tribes, namely, the articulated structure of the external parts of the body, which being of a corneous texture, serve as supports for the muscles and other internal organs, just as the internal vertebrae of the higher animals support the same parts; so that in these portions of the invertebrata, the external covering may properly be regarded as the skeleton. Now this character joined to those derived from the respiratory, nervous, and locomotive systems, tend to separate the true articulated animals from a great number of other small creatures, with which, under the common name of insects, they are classed, even in some of the latest popular compendiums of natural history which have issued from the press, in which the leech and snail, together with many of the still lower animals, are introduced, without even a sectional note of distinction, amongst insects.

If we look around, on every side, in every place, and in every season, we behold the immense profusion with which nature has scattered the objects of our present meditation over this world of ours. The earth, the water, and the air, teem with insect inhabitants; every vegetable supports numerous colonies; the diminutive fungus and the gigantic oak are alike subject to their attacks; and as a proof of the vast extent of the series, it may be added, that Saint Pierre tells us, that several hundred different species of insects visited a small rose-tree placed in the window of his study, whilst a single forest tree is the abode of numerous tribes and families. In like manner they cease not in their attacks upon animal matter, both in a dead and living state; and, as we have already had occasion to mention in these pages, man himself, the lord of all, is not exempt

from annoyances from them. How necessary, then, from the insurmountable difficulty resulting from the almost infinite numbers of these creatures, is it that we should bespeak the indulgence of our readers in our attempt to lay before them, in as concise a manner as possible, a sketch of the insect world. It is not difficult to imagine the painful nature of the researches necessary for obtaining a knowledge of the internal anatomy and other peculiarities of creatures, of which by far the greater portion do not exceed an inch in length. And here it is that we, in the most especial manner, discover the invaluable worth of the microscope, that surprising instrument, by which the minute wonders of the creation are brought as vividly before the eye of the observer, as are the wonders of the celestial sphere by that other philosophical wonder, the telescope. These instruments are now, it is true, no novelties; but we know no more striking instances in which the powers of the mind have worked a victory over nature.—Speak of the powers of the steam-engine, and the many hundred times by which the manual forces of the human frame are increased by its operations—and what is this in comparison with the tens of thousands of times to which the ordinary size of the meanest insect is increased by the assistance of the microscope? Still the continued employment of this instrument is a painful operation, increased a thousand fold by the minuteness of the objects, and the extent to which it is necessary to carry the investigation of them. Look at the unwearied labours of Lyonnet, which were for years devoted to the anatomical examination of a single insect; or of those of Straus-Durckheim, whose memoir upon the cockchafer exhibits almost an equal endurance of observation. If, moreover, we consider that not only does an insect combine within itself the systems of respiration, circulation, digestion, secretion, and sensation, analogous to those of the higher animals, but also that owing to the remarkable circumstance that the majority of these animals undergo a series of transformations, whereby these systems are completely altered several times in their progress to the perfect state, it is essential to extend our observations to every period of the life of the animal, before we can arrive at a perfect knowledge of its structure, so as to enable us to form a proper estimate of its comparative anatomy; we cannot, therefore, but admit that the difficulties attending the labours of the entomologist are not fewer than those in any other department of nature; difficulties, which, from their very nature, cannot cease to arouse the attention of the devoted lover of nature. And hence arises the necessity of our having recourse to the labours of our predecessors in the vast field opened to us, and in the works of Swammerdam and Lyonnet, De Geer and Reaumur, Latreille and Kirby, we find the materials, not for a short essay, as ours must be, at its greatest extent, but for volumes upon volumes.

Of all the classes of zoology, then, that of insects is the most numerous, the most beautiful, and the most varied; and though it cannot be denied that no portion of the science presents to those who are ignorant of its merits, so many apparent points of repugnance; yet which, nevertheless, so much captivates the attention the more its merits are examined. It is, indeed, for those who undertake its investigation, an unceasing source of instruction and of pleasure, open to all, requiring not, like the classes of quadrupeds or birds, great pecuniary sacrifices in the col-

lection of materials; but yet possessing for every observer a still unopened mine of knowledge, even in the very commonest species. Volumes have been written upon the bee; but still how many wonders of the hive remain unexplained? The domestic fly swarms in every apartment, and yet how many points in its economy are uninvestigated? And, which is not less peculiar and interesting to the student of the insect world, he may pursue his observations without pain to the objects of his research; he may watch them at their occupations, observe their manœuvres, and contemplate the beautiful harmony which exists between their organisation and their economy, and leave the contemplation "a wiser and a better man." Here he will find life in its widest extent; sensation and motion are here bestowed to a degree

Muscular system of the caterpillar of the goat moth (*Cossus ligniperda*).

even far exceeding that of the higher animals; and it is this which constitutes one of the greatest charms of the pursuits of the entomologist. The botanist may boast of the splendour of his flowers, the conchologist may glory in the beauty of his shells, and the ornithologist in the interesting economy of his birds; but the entomologist can do more, since the objects of his pursuit are not less splendid than flowers. Indeed, what flower can vie with the brilliant butterflies of South America?—Neither are they less beautiful than the most beautiful shells—for what shells can vie with the splendid coatings of the *Chrysididae*, or with the extraordinary forms of the *Dynastes*?—Neither are they inferior to the feathered tribes in their varied economy, whilst the very circumstance of their infinite numbers and ubiquity renders their observation a matter of comparative facility. If we notice them with reference to the latter peculiarity (that of their varied economy), we find them occupied in works as varied as those of the most consummate mechanic and artist. Here we find one suspending itself by a series of mechanical motions, by one extremity of the body, whilst others keep themselves from falling during their state of inactivity, by passing a cord round the middle of the body; here some construct, for the like purpose, a bed of the finest silk, whilst others, with the greatest ingenuity, form their domicile of other and very differ-

ent materials, differing in the different species, whose economy is consequently different. Some unite to form a common lodging, whilst others separately incase themselves in a coat of wool as soon as they are born. In many instances the patient care of the female in the construction of her nest, and in the preservation of her offspring, is not surpassed by the highest amongst animals. In all these things, and in the infinite diversity of means exhibited by insects tending to one common end—the preservation of each—the supremacy and wisdom of a Divine Intelligence, creating all things—preserving all things—directing all things—are so pre-eminently conspicuous, that it is impossible, even whilst paying but the slightest degree of attention to such things, to overlook the sublimity of the science, nor not to be filled with the most profound respect for the all-powerful wisdom and goodness of the Creator, and, even in the midst of the most profound grief, it is impossible to contemplate these wonders of the creation without an assuagement of our pain.

If, moreover, we would institute a comparison between the objects of our present contemplation, and those of the higher ranks of nature, we shall find here assembled all those striking peculiarities which abound in the latter; the piercing eye of the lynx and the falcon, the hard shield of the armadillo, the splendid tail of the peacock, the imposing horns of the stag, the swiftness of the antelope, the fecundity of the hare, the architectural powers of the beaver, the climbing powers of the squirrel, the gambols of the monkey, the swimming of the frog, the burrowing of the mole, and the leaping of the kangaroo; all these things are found amongst insects, and often, indeed, in a redoubled degree. Then, the eye of the fly, with its thousands of lenses, the horns of the stag beetle and dynastes, the splendour of the scales upon the diamond beetle, the hard covering of the beetles (whence even their ordinal name, *Coleoptera*, wings in a case), the admirably constructed works of the hive, the maternal cares of the spider, which guards its bundle of eggs with incessant care, carrying them about with it beneath its body; the ingenuity of the cocoon of the emperor moth, constructed with an elastic aperture, preventing the entrance of enemies, but allowing exit to the inhabitant; the numberless progeny of the aphid, the powerful flight of the locust, the leap of elater and grasshopper, the brilliant light of the glow-worm, the instinct of the burying beetles (*Necrophagus*), the mottled jacket of the larva of the clothes-moth, formed of different coloured wool, or the excrementitious covering of the larva of the *Casida*, the frothy abode of the *Cercopis*, the abandoned shell inhabited by the hermit crab, and the extraordinary gall residences of the *Cynipidae*; all these, and a thousand other not less interesting circumstances exhibited, and to be exhibited more at detail in our pages, cannot fail to convince the reader that the class of insects does not possess fewer claims to his attention than any other of the classes of nature.

The continued action which insects exercise upon the other productions of nature (and we may mention, in passing, as a most conclusive evidence of such action, that the island of Grenada is now reduced to a ruinous state owing to the attacks of the diminutive cane-fly upon the canes, having extended nearly throughout the island), the insurmountable power of these enemies, owing to their minuteness, the injuries which they inflict upon our possessions, animal and vegetable, the benefits arising from many of them, their extraordinary forms and transforma-

tions, rivalling the most striking creations of fable, the complexity of their organisation, external and internal, their inconceivable industry in the construction of their nests, and the foresight which they manifest in their self-defence, all teach us that entomology is well worthy of the attention of the observer of nature.

But it will be said, why devote our attention to objects so minute? We reply, if the colossal alone be worthy of notice, search elsewhere for the objects of your notice, for here the objects are so small, that the full stop at the termination of this sentence, is much larger than many of the species. But to the eye of philosophy, what matters colossal size and gigantic expanse? The wisdom of the Creator is concentrated in these minims of creation, in order the better to develop his power; since in these creatures, whose excessive minuteness renders it difficult, and even impossible, to observe some of them with the unassisted eye, how can we conceive it possible to arrange all the machinery which exists in the bodies of those little creatures, as perfect and as complex as in those of the largest? The little beetle (*Atomaria atomos*), and the minute parasitic fly (*Myrmomonas*), although not one-hundredth part of an inch in length, possess precisely the same number of organs, and even of joints of those organs, as their larger brethren of the classes to which they respectively belong. To neglect this portion of the creation is to say, that these living machines, in which the rules of the most perfect mechanical knowledge have been implicitly followed, and of which the various parts are arranged with the utmost art, but which are nevertheless so fine and delicate as to escape our view, are less worthy of regard than the larger machines made precisely upon the same model. Absurd reasoning! Who does not regard skill of the artificer capable of forming a minute pocket watch with its delicate machinery, as more worthy of notice than that of the workman who can but construct a town clock?

Such being the claims which the objects of the entomologist's care possess upon his attention, we therefore proceed in the present article to state the most efficient modes of research, whereby also, the most satisfactory and pleasing return may be obtained for the toils of investigation, premising that we deem all animals destitute of internal vertebræ, having articulated bodies, and articulated legs in the perfect state, to be insects; following, therefore, in the steps of Linneus and Latreille, we consider *Crustacea*, *Arachnida*, *Acar*i, and *Myriapoda*, as much entitled to the attention of the entomologist, as beetles, bees, or butterflies. Our reasons for this view of the subject, together with a general sketch of the anatomy and classification of the whole, will therefore more properly fall under the general article, *Insects*; the present article being confined to the preceding remarks upon the general claims of these minute animals to a share of the notice of the zoologist, to a sketch of the plan of study to be adopted, and to a view of the rise of entomology as a distinct branch of zoological science, from the earliest ages to the present time.

Entomologists, like the objects of their research, may be classified. First, there is the amateur, whose sole object is the procuring, either by capture or by purchase, of a collection of handsome insects, either to be placed in drawers, without any other arrange-

ment than that of beauty of colour or size, or in glazed picture-frames to be hung up in his room. This, it is true, is the lowest class of entomologists; but the labours of such amateurs are not without pleasure to themselves, and are sometimes serviceable to the science of entomology. The author of this article, who has been for days confined to the desk in the centre of this vast metropolis, can testify to the delightful sensations with which he has inhaled the breeze upon Shooter's-hill or Wimbledon-common, when on the way to those well-known entomological spots, Dareuth and Coombe Woods; whilst the best practical collector whom we have ever heard of is Daniel Bydder, a Spital-fields labourer, by whom some of the most interesting of our English insects were first discovered. And in like manner Joseph Standish, a Brixton cobbler, from a pure love of entomology, taught himself to draw and paint insects; and having followed up this pursuit, during his leisure of many years, he has acquired the art of giving to his figures of moths, a beautiful downy appearance, so like nature, that we have known a volume of his drawings sold for many pounds. Can it be denied that if, amongst the lower classes, the collecting of objects of nature, and such-like pursuits, were more general, the vice of drunkenness and the reign of gin-palaces, would be over?

It is not, of course, our intention, in this work, to lay down an account of the instruments required, or the modes of collecting insects for the information of the mere collector. These will be found in Kirby and Spence's Introduction, in the "Insect Miscellanies;" or in Mr. Ingpen's little manual devoted to this subject. Suffice it to say, in this place, that when captured and killed, either by immersion in scalding water (as is usually done with beetles) or by being placed in a close small box with bruised laurel leaves (as is very serviceable with flies, moths, &c.), the insect is stuck through one of the wing-cases (if a beetle), or between the wings (if a fly or moth), with a pin proportioned to its size; the entire collection being preserved in chip-boxes, or in a cabinet of shallow glazed drawers; having the bottom lined with cork and covered with paper.

Instruments for collecting Insects.

A, The large gauze flap net. B, the sweeping or water net. C, the gauze forceps. D, the collecting bottle for holding small beetles, &c. E, the breeding cage.

Various kinds of nets are employed in collecting insects, such as the flap-net, for catching insects on the wing, made of fine gauze, resembling a bat-fowling net, and the sweeping net, for catching insects on grass and low herbage, made of strong canvas, and resembling a landing net. When secured, the insects are either immediately pinned, or carried home loose in quills or glass bottles. After they are killed and pinned, their limbs are arranged in a natural position by means of pins and bits of card, by which

they are retained in their places until they are dry enough to be placed in the cabinet. Caterpillars are kept in boxes with gauze sides, and fed with leaves of the peculiar plants upon which they are found, until they assume the chrysalis state; and in this manner moths and butterflies are procured with their plumage much more beautiful than when captured at large. Insects which may have become stiff before they have been displayed, are readily relaxed by placing them upon damp sand for a few hours. It is necessary that the store boxes, or cabinets, containing insects should be kept in a dry situation, otherwise the specimens soon become mouldy. It is not advisable to place them against an outside wall of an apartment; moreover, it is necessary that camphor should be kept in little cells in the drawers to prevent the attacks of mites or other insects, such as the *Anthreni*. (See *DERMESTIDÆ*.)

These hints will suffice for the practical collector and the professed amateur; for the more systematic entomologist, who is not content with merely collecting insects, but who is intent in classing his collections, arranging each in its proper place and under its proper name, and describing such as are nondescript, another plan of study is requisite. Of the nature of the pursuits of this class of entomologists, Messrs. Kirby and Spence, having previously spoken of them as possessing an agreeable and unfailing provision of that "grand panacea for the tedium vitæ" employment, make the following observations, "with what view is the study of the mathematics so generally recommended? Not certainly for any practical purpose,—not to make the bulk of those who attend to them astronomers or engineers, but simply to exercise and strengthen their intellect,—to give the mind a habit of attention and investigation. Now for all these purposes, if I do not go so far as to assert that the mere ascertaining of the names of insects is equal to the study of mathematics, I have no hesitation in affirming that it is nearly as effectual, and, with respect to giving a habit of minute attention, superior." Examples are then given of the necessity for minute discrimination in the examination of insects for the purpose of discovering the proper name of each and the descriptions to be given of it, if it should happen to be undescribed: but there is still another advantage to be gained from this kind of investigation. We will assert that no one who has studied the classification of insects, commencing with the class and going regularly through the orders, sections, families, genera, down to individual species, and neatly arranged his insects in his cases, can leave the subject without having gained certain principles of regularity and order, which will communicate themselves to his every-day employment, inducing a methodical correctness and precision in the details of life, which are so superior to the careless proceedings of the thoughtless and irregular.

By the student, therefore, who would attempt the classification of his collection, it is requisite that a progressive series of inquiries should be made. It is not fit that he should commence by the investigation of isolated species, his collection must be in the first instance generalised, since it is only by studying groups of insects in the mass that we can ever acquire any general views of the science. If this be not done we shall be constantly falling into the error of separating intimately allied groups, because their external appearance is different, and of uniting insects which,

from the difference of their organisation, are widely apart, because their appearance is similar. Let us take any every-day example of the want of this generalised view of insects; there is an extensive group of two-winged flies which are called drones, they are the very personifications of luxurious idleness, they do nothing but sip the nectar from the brightest flowers, and enjoy the sunshine basking upon the leaves of plants; and there is an extensive group of bees, having the same general appearance, but being in habits the very reverse of the drones; toiling all day long, either in the construction of the nest or in provisioning it with pollen paste. Now by ignorant persons the same name is given to both groups of insects, and not the slightest idea is entertained of the totally opposite nature of their habits.

A, Drone-fly (*Eristalis*). B, Spring Wild-bee (*Anthophora rectus*).

We are the more anxious to impress upon our readers the necessity for obtaining a generalised view of insects, and indeed of the entire productions of nature, because we know that many of our fellow labourers fritter away their talents and time in the sole elucidation of the characters of obscure species of insects, without a thought of the higher views which lay open before them. "English naturalists," says Mr. Bichenov, "appear to me, from various causes, to have pursued the nomenclature and examination of species in such a way as very much to exclude from their attention the higher ends of science, in which alone the bulk of mankind is interested. Ever since the subject has been pursued in the spirit of true philosophy, it has almost solely been confined to the analytic form which, however important, is apt to degenerate into unprofitable detail, as the synthetic mode leads oftentimes to the other extreme of loose and impracticable generalisation." "The necessity of knowing particulars has made our researches into species very minute, and has given to our operations in the eyes of the multitude rather a puerile cast. The method by which the name of an unknown species and all that has been written about it can be discovered necessarily involves such minute discrimination, that it cannot escape this superficial objection. It is however an inconvenience not incident to our subject alone, but to all the sciences more or less which require a minute examination of particulars." And he concludes by observing, "I am anxious not to be misunderstood; I do not want to disengage naturalists from attention to the analysis of species, or to absolve them from the labour of minute investigation which, after all, is our chief business; but I do wish to see them following nature through all her varieties with a view to generalise as well as particularise; to relieve the memory from the overwhelming multitude of names which the discovery of new species has imposed; and to compress the result into a size adapted to the human capacity. This may safely be pronounced to be among the highest efforts of a created intelligence."

Hence will be seen the necessity for studying collections of animals, and particularly of insects, in the mass; for though the knowledge of species, as Mr. Kirby has well observed, is indispensable for the registry of facts and other practical purposes, yet the knowledge of groups leads to a higher wisdom; and indeed it is through these that we best descend to the study of species. The first thing, therefore, requisite is, to ascertain to what order of insects any individual specimen may belong. For this purpose an inspection of the mouth (for the purpose of ascertaining whether it is furnished with jaws or with a sucker), and of the structure of the wings, will generally suffice. The next step is the separation of your collection into the primary sections and families of which the orders are composed; and here, of course, the characters will vary in the different orders, for instance, in the order of beetles (*Coleoptera*), the primary sections are founded upon the variation in the number of joints in the tarsi (or last articulated part of the leg); whereas in the two-winged flies (*Diptera*) this character is constant, and the number of joints in the antennæ constitute the leading characters of the primary divisions. For the families no better rule could be laid down than to study the characters of the Linnæan genera, which in fact correspond generally with the modern families of insects; but as we have already stated in several of our entomological articles, the contents of these groups have so immensely increased since the days of Linnæus, that it has become necessary to subdivide them into minor divisions, to which the names of genera and subgenera have been given; and here it will be necessary to have recourse to such authors as Fabricius and Latreille, Stephens, or Curtis, for obtaining an idea of the extent to which these subdivisions have been carried, as well as for obtaining a knowledge of the various subdivisions themselves. The practised eye, indeed, can readily reduce an extensive family of insects into its sectional groups without any other assistance than that derived from long experience, because the most nearly allied species possess such a general resemblance to each other, that it is almost impossible to overlook their relationship; for instance, the restricted genus *Carabus* comprises a very extensive series of ground-beetles, varying but little in size (compared with the variations in size which occur in the family), being moderately large, and ornamented more or less with metallic tints; so also among butterflies, the genus *Colias* comprises species being generally of a brimstone colour. We now arrive at the investigation of the specific name of the insect under examination, and here lies a great difficulty, owing in general to the number of species; great relief, however, is afforded by the introduction of subdivisions in the longer genera, by which we arrive almost immediately at the name of the species itself. In general the descriptions of insects are written in Latin, or at least, if an author chooses to give a specific description in his native tongue, it seems by common consent and usage to be required that he should commence his descriptions by a short Latin character, which, from the almost universal employment of that language in works of natural history, is intelligible to naturalists throughout the world. Moreover, the indication of the natural length and expansion of an insect, the addition of the country which it inhabits, and the references to the works of other authors by whom the species may have been described,

and especially where it has been figured, all tend to render this branch of the science less intricate than it at first appears. If, however, after all research into the works of those authors who have especially devoted their attention to the family or genus of insects, to which the one under examination belongs, it should be evident that it is a nondescript, its description, embodying the points of distinction which it presents with reference to the already described species, and whether resulting from structural variation, or from differences of colour, or of striation or punctuation (as in the beetles), may be attempted, taking as models the specific descriptions contained in such admirable monographs as those of Mr. Kirby upon the English bees, or the genus *Apion*, or that of Latreille upon the ants.

But the investigation of species, although valuable for the sake of precision in the identity of the object which is the subject of observation, is by no means essential for enabling us to study the structure or economy of an insect, and this brings to our notice several other classes of entomologists, who more especially merit the title of philosophical observers of nature. Of these the out-door naturalist first claims our attention. Instead of running from one end of the country to the other, climbing mountains and descending valleys, stopping only so long as may be necessary to transfix the luckless objects of his chase, and deeming himself happy only when his collecting box is filled with specimens, the real observer of nature finds materials for study even at his own door. The former, it is true, meets with many rarities, and even perhaps nondescript species, but notwithstanding all his toil, has he observed a single fact relative to the history and economy of a single insect? Swammerdam and Reaumur toiled not thus, and yet their labours are read even now by all the world, whereas the labours of the collector are but at best selfish, and the descriptions of his new species read only by a few amateur collectors like himself.

Seek then a spot favourable for the habitations of insects—a sunny nook in a wood, a hot sandbank, or the margin of a stream, and watch the proceedings of the numberless insects which frequent these spots.

Examine, for instance, the clear water, and watch the movements of the various aquatic insects with which it abounds; and especially observe the silvery silky globe which the diving water-spider bears about with it, and in which, in an enlarged form, it passes the winter. Observe the mode in which the insect,

Diving water spider, in its diving bell, fixed to plants at the bottom of the water.

resting upon a flower, extracts the honey from its cup; trace the flight of that sandwasp, and notice the peculiarities of its manoeuvres in the construction of its burrow; examine with careful eye the movements of that sawfly in the act of forming a channel in the sprig in which to deposit its eggs; or listen to the

chirping of the field cricket, and trace it to the burrow, at the mouth of which it sits ready to dart upon its prey.

Notice these things, and then say whether these and a thousand other observations of a similar nature are not infinitely more interesting than the mere pursuit and capture of specimens, or the dry technical detail necessary for their specific determination.

"Those who have studied nature only in books," observes St. Pierre, "can see only their books in nature, they look upon the natural world only to find therein the names and the characters of their systems. If they are botanists they are satisfied to have discovered a plant of which some author has spoken, and having assigned it to the class and the order which he has pointed out, they gather it, and spreading it between two bits of grey paper, they sit down content with their knowledge and their researches. They do not form a herbal to study nature, but they study nature to form a herbal. It is in the same way that they make collections of animals, that they may learn their genera and species and treasure up their names. But can he be a lover of nature who thus studies her wonderful works? How great a difference is there between a dead vegetable, dry, faded, discoloured, whose stems and leaves and flowers are crumbling to powder, and a living vegetable, full of sap, which buds, flowers, gives forth perfume, fructifies, and sows itself again—maintains an universal harmony with the elements, with insects, with birds, with quadrupeds, and, combining with a thousand other vegetables, crowns our hills and adorns our banks. The animal loses by death even more of its characteristics than the vegetable, for the animal has received a more vigorous portion of life. Its principal qualities vanish; its eyes are shut, its pupils are dim, its limbs are stiff, it is without warmth, without motion, without feeling, without voice, without instinct. What a difference between the animal who enjoys the light, distinguishes objects, moves towards them, calls the female, couples, makes its nest or lair, brings up its young, defends them from their enemies, congregates with its kind, and gives music to our woods, and animation to our meadows."

But the out-door observation of these and such like subjects by the real lover of nature—and no one merits this name who does not bestow attention of this kind upon the objects of his research, leads to far higher considerations and views. Peculiarities of economy, and herein almost every species of animal differs from its neighbour, necessarily imply corresponding peculiarities of organisation, often indeed minute, and to be sought after with great care and labour, often with the assistance of the microscope. The philosophically minded student will therefore combine with the observation of habits investigation of structure, and in this latter particular lies the merit of such laborious naturalists as Lyonnaer, Swammerdam, or Straus-Durckheim, who lay open to our view the minute intricacies of the internal anatomy of various species of insects. The following observations upon the connexion between these two branches of our subject, from the Introduction to the Menageries, will be read with pleasure, from the soundness of the views which they inculcate. "It is amazing how much quickness the habit of observation will impart to the whole intellect, and give it an aptitude for understanding and enjoying the thing observed. There is nothing, for instance, so common as to find

men wanting in a perception of picturesque beauty, of that feeling which enables some to take great delight in a landscape, not only for its extent, or the grandeur of its parts, but for the harmonious arrangement which is necessary to the effect of a picture, or for some accidental circumstances of light and shadow, or of colour, which render the prospect more than usually attractive. Now this is strictly an acquired faculty, and one which is produced by the practice of looking at nature or at the monuments of art, with the previous adaptation of the vision to picturesque objects; and a person who enjoys the faculty (we say enjoy, for it is a source of real pleasure) is said to possess a painter's eye. It is precisely in the same way that a naturalist, by constantly observing the peculiarities of animal life, acquires the readiest perception of the differences in the structure and habits of the great variety of living beings, and he perceives in each of them qualities which a less practised observer would entirely overlook. Through these habits of observation, the science of zoology, which comprehends all that relates to the description of classification of animals, has been gradually established. By diligent observations the peculiar structure of vast numbers of individual animals has been ascertained, their habits have been accurately described, and many ancient errors, which arose from hasty examination, have been exploded. Thus, in the more recent scientific works on zoology, the accidental circumstances of size or colour, or locality, or any identity in unimportant habits, have ceased to be guides in the classification of animals, but the *essential peculiarities of their formation, which chiefly determine their habits*, have alone been regarded. We mention this, to point out that the actual observations of successive naturalists, leading to the accumulation of a great body of facts, have principally contributed to the advance of zoology as a science in modern times, for the science being wholly founded upon observation, and not upon previous calculations, or any series of experiments, the greater our collection of facts the nearer have we approached to systematic perfection."

These views so fully coincide with our own opinions of the necessity for continual observation of facts, that we have not hesitated to introduce them into this article, although they are equally valuable with reference to every department of zoology. The observation of facts has been too much neglected amongst us; there is, however, one passage contained in the above extract, which appears to us to call for further notice. We are there told that "the *essential peculiarities of formation chiefly determine the habits*" of animals, and a little further we meet with the remark, that the systems of Cuvier, Blumenbach, and others, are founded upon a consideration both of the teeth and of the organs of touch, and therefore, "being formed with especial reference to the two great distinctions which determine the most important habits of the animal, are called natural systems."

Now this passage, and numerous others which we might quote from the works of other modern writers, both popular and scientific, to the like effect, appear to the author of this article to result either from very incorrect ideas of the system of nature, or from a carelessness of expression which leads us to imply the existence of such incorrect ideas. Let us not be misunderstood. These passages seem to us to imply that, in the opinion of the writers, a certain form-

ation being bestowed upon an animal, certain peculiarities of habit dependent thereupon are acquired. Observe the result:—if we adopt this mode of looking at the operations of nature, do we not immediately fall into one of the worst errors of some of the worst of the French philosophers? Do we not at once virtually deny the existence of design in the creation? It was upon this very point that our great philosopher John Ray contended with such eloquence in his "Wisdom of God in the Works of the Creation." Against the doctrine that the bodies of men and all other animals were the effects of the wisdom and power of an intelligent and almighty Agent, and the several parts and members of them *designed to the uses* to which now they serve, the atheist, he observes, has one subterfuge, in which he most confides, viz. that all these uses of parts are no more than what is necessary to the very existence of the things to whom they belong, and that *things made uses, and not uses things*, and in this spirit Lucretius says,

—Nil ideo natum est in corpore ut uti

Possumus, sed quod natum est, id procreat usum :

And again—

— Omnia denique membra

Ante fuere, ut opinor, eorum quam fuit usus.

So that, in the opinion of the atheist, all this admired and applauded usefulness of their several fabrics is but a necessary condition and consequence of their existence and propagation.

If it could be proved that the doctrine contained in such passages as those we have quoted, ought not to be identified with the atheistical doctrines above alluded to, and refuted so ably by Ray, we would not have noticed the subject in this manner; but when it cannot be denied that the only interpretation to be put upon the former coincides so exactly with the latter, we think it our duty to guard our readers, and especially our younger readers, from unheeding falling into a train of thought in which the fore-knowledge and harmonious contrivances of an all wise Creator, with reference to preconceived and intended uses, are virtually denied; attributes which it is expressly within the duty of the zoologist to hold up to contemplation and admiration, and which the objects of his study so continually present to his view.

Instances of structure dependent upon economy: A, fore leg of the mole cricket, formed for digging under ground, the articulated tarsus, *a*, being lodged in the groove, *b*, when in action. B, fore leg of a sand wasp, formed for burrowing in loose sand; the alse, *a a*, being employed in brushing away the loose particles.

We have purposely abstained from entering into the arguments adduced by Ray in refutation of these atheistical opinions, the opposite view being fortunately too clear to need much argument in its support. He would be but a sorry architect who, having completed the building of a splendid palace, had not, previously to its erection, planned the uses of its various apartments, and adapted the size and situation of each to its intended uses.

NAT. HIST.—VOL. II.

We have thus seen that it is by the continued accumulation of facts, and by noticing the adaptation of structure to habits, or, as Ray more quaintly styled it, the making of things to uses, that we obtain more decided chances of attaining to perfection in our systematic classifications. But we are enabled to do more than this. Natural history is not a mere science of system and names; we have living objects for our study. The student must, however, guard against both extremes. It is as erroneous to consider that person a true naturalist who contents himself with giving a series of hard names to a collection of dried insects or other objects, as it is to assert "that any person, with a little care, may become a tolerably good naturalist the first walk he takes in the fields, without much knowledge of books."

To observe well the habits and economy of animals, to notice, by the assistance of anatomical examination, the adaptation of structure dependent upon such habits, to have studied the writings of our predecessors who have pursued a similar mode of research, and to apply the information thus obtained to the discovery, not only of the systematic name, and the relationships, more or less remote, existing between the various species of animals, with reference to their arrangement in a natural system\*, but also of their relationship with nature in general, the weight of each in the great scale of the universe, and the mutual dependence of animals or plants upon each other, which constitutes that mighty whole which St. Pierre has so well termed the harmony of nature; this it is which constitutes a knowledge of nature, and he, and he only, who will look at an insect or a plant in this manner,—he who will not rest contented with the possession of a specimen, or the observation of a fact in its economy, or the knowledge of its name and place in the system, but will give to his views this extent, he only is the good naturalist.

Having thus laid before our readers a notice of the various grades in the science of entomology, or rather, we might say, in any of the departments of zoology, together with what appears to us to be the most efficacious mode of pursuing the subject in each, we now purpose to trace, as concisely as possible, the rise of entomology, including a sketch of its present state.

The names of various celebrated men who have given from time to time an impulse to the science of entomology, or who have rendered to it the most signal services, mark the eras of the more remarkable periods in its history. This order, founded upon the growth of knowledge, is certainly preferable to that established upon the lapse of years from century to century.

Without dwelling upon the Book of Holy Writ, from whence it is evident that the Hebrews had a certain knowledge of the habits of various insects, and had distinguished a certain number of them, the first memorable era is that of Aristotle, since it is in

\* Some persons have either wilfully or ignorantly confounded the mere methodical classification of animals, i.e. their system of names, with the natural system, than which no two things can be wider apart. Thus, in the former, that classification must be the best by which we are enabled with the least labour to arrive at the name of an animal; whereas perfection in the latter can only result from a knowledge and adoption of the numerous and intricate relationships existing amongst animals, whether of affinity (that close relation existing, for instance, between a hive bee and a humble bee,) or that more remote relationship termed analogy, of which an instance may be mentioned in the hornet, the hornet sphinx, and hornet asilus.

the writings of that father of zoology that the first traces of entomology, as a distinct science, are to be found. This era dates from three centuries and a half before the Christian era; and, as Latreille observes, it is not less memorable in the history of the world as being that in which one of his pupils, Alexander the Great, flourished; and, by a remarkable coincidence, the modern Aristotle (as Cuvier has been called) flourished during the reign of a man scarcely less celebrated than Alexander. Aristotle noticed the difference between masticating and sucking insects, and many of the divisions which he established amongst insects are adopted by the latest entomologists; but the distinctive character of the science of entomology of this period was the admission of a greater number of insects as distinct species, which were but in the preparatory state of others, which were also observed. In like manner many species which had not been traced to the egg-state, were regarded as the offspring of a spontaneous generation. With insects were arranged the *Annelidæ* and many other animals of a widely different structure. Entomology was, however, at this period but a summary of popular traditions, often fabulous or in part erroneous, and more under the domain of medicine than of zoology, mixed up, nevertheless, with some facts which were too apparent to escape the simplest investigation. As to the other ancient naturalists, they have scarcely added any thing to the knowledge transmitted to them by Aristotle. This knowledge passed from the Greeks to the Romans, and from them to the inhabitants of the northern parts of Europe, by whom the Roman power was broken down. Pass we, therefore, over a period of nineteen centuries, and arrive at the second great entomological era when the revival of letters led to a corresponding revival of the so long dormant sciences. Albert the Great devoted one out of the twenty-two folio volumes, of which he was the author, to natural history, and in which he treated upon insects, which he separated from the crustacea. Half a century afterwards (about 1550) the simultaneous appearance of Gesner, Belon, and Rondelet, three of the fathers of zoology, gave a great impulse to this branch of science. Still, however, entomology was much infected with the radical vice of spontaneous generation, but the spirit of observation was abroad; facts were collected, and both by the assistance of figures engraved upon wood and of microscopic glasses, much increase was made to the stock of knowledge. Some naturalists even confined their researches to entomology; and in 1602, Aldrovandus published a treatise upon this science. In like manner, in the "Treatise of Insects," (an extensive folio volume, being the joint labours of Wotton, Gesner, Penny, and Mouffet, published in 1624, and being remarkable as the earliest work which appeared in England expressly devoted to entomology), a great variety of figures of insects were given, which from their rarity have been overlooked or regarded by modern writers as entirely novel. The work was divided into chapters, in each of which some genus of insects was treated upon; the first seven being devoted to the honey bee. Still, however, there were incongruously blended along with insects all sorts of larvæ of other species belonging to the winged orders, and likewise many of the Linnæan class of genuine *Vermes*, and even the *Hippocampe*. Moreover, in the works of this period, we find the same continual reference to the supposed

medical virtues of almost every species of insect, an instance of which, showing the ridiculous extent to which these ideas were carried, has been given under our article *Curculionidæ*, in the account of the *Curculio antidontalgicus*. But better days were now at hand. Redi, and Malpighi, and Swammerdam, towards the close of the seventeenth century, laid the foundations of a true system of entomology by the excellency of their respective observations. The first of these celebrated men, by experiment, threw down the doctrine of equivocal or spontaneous generation, and also corrected numerous other errors into which naturalists in general had fallen. The second published a variety of researches of great importance upon the anatomy of these animals; whilst the third, by stripping from the transformations of insects all of the marvellous with which they had been invested, and more especially by the clearness of the details by which he illustrated the extraordinary and startling fact which he quaintly designated as "an animal within an animal," contributed more to the true knowledge and systematic distribution of insects than any of his predecessors. His work, as well as those of Mouffet, Redi, and Malpighi, are still sought after with avidity by the student; and his pages, although containing much verbosity, are filled with the most valuable materials—the result of the most patient attention, devoted both to the habits and structure of the animals investigated. If, indeed, in our days, the distribution which he proposed, founded upon the nature of the transformations of insects, has been abandoned, it is not less true that the considerations upon which it was established, constitute one of the most valuable elements for a classification of insects, according to their natural relations with each other.

About the same period Lister, Leeuwenhoek, madame Merian, Vallisnieri, and Ray, rendered great service to entomology by making known, in considerable detail, a great number of insects, whilst the *Memoirs of Reaumur*, which appeared about the middle of the eighteenth century, form a storehouse of facts to which every entomologist cannot but turn with new delight. De Geer also, the prince of entomologists as he has been termed by Macleay, flourished about the same period, and either as regards classification, anatomy, physiology, or the economy and habits of insects, his "*Mémoires pour servir à l'Histoire des Insectes*," written in French, although printed at Stockholm, cannot be cited without praise. There are other authors who have trod in the steps of these illustrious men, but up to the present time their labours have not been surpassed.

We now arrive at the era of Linnæus, a name to be revered by every naturalist. To him every branch of natural history, entomology, in particular, are under the greatest obligations for the strong impulse given to them. This is not the place to detail his classification of insects, valuable as it is, and purified from the errors with which the ancients had darkened the subject; but we must here pay the debt of justice and of gratitude for the admirable system of names which he invented, and which has now become general, for the clearness and precision of the definitions which he gave of the different orders of insects, for the establishment of genera, and for the promulgation of a code of philosophical precepts relative to natural history and botany.

The same era gave birth to other entomologists, whose works must be cited with praise—Rosel, Schaffer,

Frish, all of whom have figured and described many insects. Bonnet, whose researches upon the habits and generation of *Aphides* are of the greatest interest; not only with respect to the natural history of these animals, but also to physiology in general. Lyonnnet, to whose incomparable anatomical details upon the *Cossus* we have had occasion repeatedly to refer; Fabricius, also the pupil of Linnæus, by the vast number of new species of insects which he described, and the pains which he took in bringing to perfection a novel system of classification founded upon the structure of the organs of the mouth (that of Linnæus being built upon the structure of the wings), has merited the thanks of the entomologist.

Hitherto we have seen that in the distributions which had been proposed by entomologists, a single organ, or series of organs, had been selected as a keystone of the system; the natural consequence of which, as might have been expected, was the constant artificial results to which such distributions were exposed.

We now arrive, however, at the era of the eclectic system, or that of Latreille, one of the most indefatigable and philosophical entomologists that has yet appeared, who perceiving this difficulty, successfully accomplished the task of remedying it. He did for entomology what his compatriot, Bernard de Jussieu, had succeeded in doing for botany. By making use of the various characters which are exhibited by various organs in various degrees of development in various groups of insects, and by neglecting neither the metamorphic characteristics (which were the key of Swammerdam's arrangement); nor the variations in the structure of the wings (upon which the Linnæan system was founded), nor the structure of the mouth (which Fabricius had employed as above stated), he has established amongst insects natural groups, arranged according to the affinities which they respectively possess with each other. His first work appeared in 1796; and since this period up to the present time, the works of entomologists in general have been directed towards the same end. Latreille himself, until his lamented decease, ceased not to strive to render his views more accordant with nature. Cuvier, by his admirable comparative anatomical researches; Dumeril, Lamarck, Savigny, Macleay, Kirby, Meigen, Schonherr, and a great number of other distinguished authors, have followed in the same steps, and have contributed to render the distribution of insects more perfect, and more easily applicable; or to complete our knowledge of groups by the publication of descriptions of new species, or of anatomical details of those already known.

In respect, therefore, to precision of observation, to the distribution of insects into natural groups, and the classification of such groups, it is to be observed, that in our own times the greatest progress has been made in entomology. Earlier classifications were founded upon individual and isolated characters, so that the groups which exist in nature were but vaguely exhibited; but at the present day, by the examination of the general characters of insects, all such as are allied together in nature are brought into contact, the effect whereof is, that it is sufficient only to obtain a complete knowledge of a single individual, in order to gain a clue to the general structure of the whole of the species which are arranged with it.

In like manner, the investigation of the internal anatomy of these animals has been equally progressive, for, instead of simply examining the structure of such

or such an isolated animal, entomologists, following in the steps of the comparative anatomists, have traced the modifications which each organ exhibits in the whole of the animals of which the class is composed. Cuvier led the way to this branch of the science, and has been followed by Marcel de Serres, Herold, Treviranus, Leon Dufour, Gaede, &c.; whilst the minute researches of Straus-Durckheim upon the *Melolontha vulgaris*, and of Mr. Newport upon the Privet Hawk Moth, published in the "Philosophical Transactions" for the last year, may be cited as models of patience. Besides the last named author, the English entomologist may boast of the works of several other labourers, whose researches are not inferior to those of any of the continental authors. The "Illustrations of the Genera of British Insects," published by Mr. Curtis, is a work of the highest service to the science, displaying not only the most minute care in the dissection and delineation of the typical species of the genera illustrated, but also the highest style of elegance in its pictorial representations; whilst the work of Mr. Stephens, which may be regarded as a companion to the former, presents to us a far more complete series and description of the species of insects found in our own island than any other country can boast of. The "Systematic Catalogue" of the latter author is a work exhibiting the most astonishing exertion; whilst the completion of Mr. Haworth's *Lepidoptera Britannica*, the Australian Monographs of Mr. George Gray, with beautiful illustrations from the pencil of Mr. Charles Curtis, the English translation of the "Règne Animal," by Mr. Griffith and others, the work upon the *Lepidoptera* of Java, by Dr. Horsfield, together with numerous valuable memoirs published in the "Magazine of Natural History," the "Annals of Philosophy," Dr. Jameson's Edinburgh Journal, the Linnæan and Zoological Society's Transactions, the Entomological Magazine, and the Transactions of the Entomological Society of London, all prove that the spirit of entomology is rising strongly amongst us.

In the last place we may mention, as affording a most gratifying fact in the history of the science of entomology, the recent establishment of societies expressly devoted to the cultivation of this branch of zoological knowledge, both in Paris and London. England, it is true, led the way by the establishment of such a society nearly forty years ago, for the support of which the best energies of the late Mr. Haworth were in an especial manner, and for a great length of time directed; but for the last twenty years nothing had been done by it. It must, however, be admitted, that it is to the establishment of the French Entomological Society of London that we may, in a great degree, attribute the rousing of the energies of the many entomologists amongst us: the result of which has been the formation of a society established upon liberal principles, and likely to prove of the greatest service to the science, for the cultivation of which it has been called into existence. See further the articles *INSECTS*, *ARACHNIDA*, and *CRUSTACEA*, and the articles referred to in each.

**ENTOMOSTOMATA** (De Blainville). These molluscs form the second family of the first order *Siphonostomata*, second class *Brachycephalophora*. The family includes the genera *Buccinum*, *Cerithium*, *Melanopsis*, *Planaxis*, *Subula*, *Terebra*, *Ebura*, *Harpa*, *Dolium*, *Cassidaria*, *Cassis*, *Ricinus*, *Cantharus*, *Purpura*, and lastly *Concholepta*, nearly all of which were

blended together by Linnæus in his genus *Buccinum*. As each of these genera will be described in their alphabetical order, a more detailed account will be here needless. The general character of the genus, as respects the animal, has already been given under the article *Buccinum*.

**ENTOMOSTRACA** (Müller). One of the two principal sections into which the class of crustaceous animals is divided by Müller, Latreille, and other entomologists. By Linnæus, the animals comprising this division, and which are chiefly of small size, were principally arranged in the genus *Monoculus*; but the researches of various more recent authors, Schaffer, Jurine, Ramdohr, Straus, Herman, and others, have shown not only that these animals constitute various different genera, but also orders and families. They are aquatic animals for the most part, inhabiting fresh water. Some of the species, however, including the king crabs (*Limulus*, which is by far the largest species in the section) are marine. Their legs, of which the number varies, sometimes reaching more than a hundred, are well adapted for swimming, being, indeed, only employed for that purpose, for which end they are either ramified or split, or else composed of flattened joints. The branchiæ, consisting of hairs or setæ, either isolated or united, forming pencils, are attached to the legs, or to certain of them, or to the upper or lower jaws. The shell covering the greater portion of the body consists of one or two divisions, and is very slender, being often membranaceous and diaphanous. The integuments of the body are rather corneous than crustaceous, in which respect they approach the insects rather than the true crustacea. The mouth is very variable in its construction, consisting either of jaws as in the *Branchiopoda*, or of a sucker as the *Pæcilopoda*, the majority of which latter order are parasitic upon various species of aquatic animals. The young of the *Daphniæ* and some other allied genera, at their exclusion from the egg, scarcely differ, except in size, from their parents; whereas the *Cyclops*, the *Phyllopodæ*, and *Argulus*, undergo decided transformations, both in the form of the body and the number of locomotive organs; indeed, in the latter organs the uses as well as the number are altered in the passage to the adult state. The antennæ of the *Entomostroaca*, of which the form and number are very variable, are occasionally employed in locomotion. The organs of generation are situated at the base of the articulated abdomen or tail, which is never, however, terminated in an apparatus for swimming, nor furnished with appendages in its lower surface, as in the crabs and other *Malacostraca*. The eggs are either carried within the shell upon the back, or are external and borne beneath a common envelope in one or two masses at the base of the tail. In some species the eggs are capable of sustaining a long continued desiccation without losing their vitality. It is not until after the third moulting that they become adult and capable of reproduction. In a few instances it has been observed, that, as in the *Aphides*, a single impregnation is sufficient for several successive generations. This section is divided into two orders, *Branchiopoda* and *Pæcilopoda*, which see, as well as the divisions there referred to, and also the general article **CRUSTACEA**.

**EOLIDA**, or **EOLIS** (Lamarck). A molluscous animal, without any testaceous protection. The body of the animal is oval, oblong, like that of a snail, gasteropod; the head very distinct, with two or four

superior tentacula, besides two labial; the branchia are formed of a great number of small soft flexible scales, imbricated on each side of the back. The *eolis* is one genera of the first family *Tetracerata*, second order *Polybranchiata*, second class *Paracephalophora*.

**EPACRIDÆ**, a natural order of dicotyledonous plants, containing between twenty and thirty genera, and upwards of one hundred and twenty species. It is closely allied to *Ericaceæ*, or the heath tribe, and differs from it only in its anthers being one-celled, and not furnished with appendages.

The essential characters of the order are: calyx five, rarely four-parted, often coloured and persistent; corolla hypogynous, monopetalous, the tube sometimes five-parted, the limb five, rarely four-cleft, sometimes bursting transversely, in consequence of the cohesion of the segments, deciduous or withering; its æstivation valvate or imbricated; stamens generally equal in number to the segments of the corolla, and alternate with them; filaments inserted on the petals or hypogynous; anthers simple, with a single receptacle of pollen; ovary sessile, usually surrounded at the base with five distinct or connate scales, and generally many-celled; ovules solitary or indefinite; one style; stigma simple, or sometimes toothed; fruit either a drupe, a berry, or a capsule; seeds with albumen.

The plants belonging to this order are shrubs or small trees, which are often covered with simple hairs. Their leaves are alternate, rarely opposite, entire, or serrated, often stalked; their bases sometimes dilated, overlapping each other, and half-sheathing the stem. Their flowers are white or purple, sometimes blue, and grow in spikes or terminal racemes, or are rarely solitary and axillary.

They are all natives of New Holland and the islands of Polynesia, forming a striking feature in the vegetation of those parts of the globe. They may be said to occupy in Australia the place which the heaths do at the Cape of Good Hope. Many of the species are remarkable for the beauty of their flowers, and are on that account prized in greenhouses. Some of them yield edible fruits, but in general their properties are not known.

The order has been divided into two sections: 1. The true *Epacrideæ*, including the genera *Epacris*, *Sprengelia*, &c., in which the cells of the ovary are many-seeded, and the pericarp capsular. 2. *Stypheliæ*, comprehending the genera *Styphelia*, *Lissanthe*, *Leucopogon*, &c., in which the cells of the ovary are one-seeded, and the pericarp indehiscent, rarely capsular.

The fruit of *Leucopogon Richei* supplied food to the naturalist Riche when he was nearly perishing from hunger in Southern Australia. The fruit of *Lissanthe sapida* is one of the few edible fruits of New Holland. It is of a red colour, and is as large as a black currant, having something of the consistence and taste of the Siberian crab. It is sometimes called the Australian cranberry.

**EPEIRA** (Walckenaer). A genus of spiders, comprising the largest and best-known British species, *Epeira diadema*, a handsomely marked species, observed in autumn suspended in its web in our gardens. We are induced therefore in this place to make a few general observations upon the order of which the spider is the type, and which were accidentally omitted in our alphabetical arrangement.

As already stated in the articles *Arachnida* and *Aptera*, the different species of spiders were placed by Linnæus in the genus *Aranea*, constituting the 8th of the order *Aptera*. These insects having, with some genera of less importance, been raised by modern naturalists into a class of equal rank with the crustacea and true insects, the Linnæan genus *Aranea* may now be considered as equivalent to an order, to which Latreille gave the name of *Fileuses* or *Spinners*, Macleay that of *Araneidæ*, and Leach that of *Dimerosomata*. The name of *Aranea* has not, however, been dropped, but has been employed to denominate the modern genus, consisting of the domestic spider *Aranea domestica* of Linnæus, and which may be regarded as the type of a group of genera to which we have applied the family name of *Araneidæ*, corresponding with the *Araignées sédentaires tubitellés* of Latreille, or those species of spiders which spin irregular webs, having a cylindric cell in one corner in which the inhabitant lurks for its prey. The spinnerets are cylindric, placed close together in a star and directed backwards, the legs are strong, the first or the last pair being the longest in some, whilst in others the legs are of nearly equal length. This family comprises the genera *Clotho*, Walckenaer; *Drassus*, Walckenaer; *Segestria*, Latreille; *Clubiona*, Latreille; *Aranea*, Latreille; (*Tegenaria*, Walckenaer;) *Agelena*, Walckenaer; *Nyssus*, Walckenaer. Latreille has also introduced the water spider, *Argyroseta*, into this group; but the Baron Walckenaer has formed it into a distinct family, which he terms *Naiades*, or *Aquatiles*.

The other groups of spiders may be arranged as follows:—

Section 1. *Tetrapneumones*, or those which have four pulmonary sacs and four external spiracles on the under side of the abdomen, (two on each side placed closely together,) and comprising the families of *Mygalidæ* (the gigantic bird spiders, as they have been erroneously termed, of tropical countries,) *Atypidæ* and *Dysderidæ*. (See *ATYPUS* and *DYSDERA*.)

Section 2. *Dipneumones*, or those which have only two pulmonary sacs and two external spiracles, comprising the majority of the order, and divisible according to the manner of construction of the web into the families *Araneidæ* described above; *Theridionidæ*, comprising sedentary species which make an irregular web without any tubular retreat; *Epeiridæ* (described below); *Thomisidæ*, hunting spiders possessing the power of walking sideways; *Lycosidæ*, wandering spiders catching their prey whilst walking about, and not making a web, except for the reception of the egg; and lastly the *Salticidæ*, differing from the latter in the agility with which they leap upon their prey from a considerable distance.

The family of the *Epeiridæ*, or the *Araignées sédentaires orbitellés* of Latreille, make their webs in a regular net, composed of a series of concentric circles, crossed by straight lines diverging at equal distances from the centre, where they in general station themselves head downwards. Some species hide themselves in a hole which they have formed near the edge of the web, which hole is either

horizontal or perpendicular. The eggs are glued together and concealed in a large silken cocoon. The spinnerets are somewhat conical, convergent, and arranged in a rosette; the legs are slender, the lower jaws are straight and thickened at the tips; the first pair of legs are the longest, and then the second pair. The eyes are disposed as follows: four in the centre, occupying a quadrilateral space, and two on each side. The genera are *Linyphia*, *Uloborus*, *Tetragnatha*, and *Epeira*.

In the genus *Epeira* the four middle eyes are arranged in a square, and the other four are placed in pairs on each side. The hooks of the jaws are folded along their internal surface, and the spinnerets are but slightly exerted. These spiders live separately, each individual forming its own web, which in some of the large exotic species, as the *Epeira clavipes*, a native of the West Indies, is sufficiently strong to hold small birds, which may by accident be caught in it; those of our own country are capable of retaining insects of considerable size, which form the prey of the spider; for this purpose they are suspended vertically between the branches of trees or plants, or in other open spaces frequented by insects: occasionally they are placed obliquely, and even horizontally, as in the *Epeira cucurbitina*. No sooner is a fly or other insect caught in the web, than it is approached by the spider, which in a curious manner envelops it in a silken shroud, by placing the tips of its fore legs, at each extremity of the insect's body, so as to form the points of an axis, round which the insect is whirled with rapidity, a dense layer of silk being at the same time thrown round it from the spinnerets. This genus is very numerous in species: M. Walckenaer mentions sixty-four species in his Table of *Araneides*, generally remarkable for the variety of their colours, forms, and economy. Of these many of the exotic species are remarkable for the singular spines and teeth with which they are armed.

*Epeira diadema*.

The best known English species is the *Epeira diadema*, which abounds in our gardens in the autumn, and which has received its name from the elegant markings of a pale colour upon the upper side of its dark-coloured abdomen. The female places her cocoon of eggs in retired corners of walls and similar situations, the young are excluded in the following spring.

We must refer to our article *SPIDER* for a general account of the mode in which the webs of these insects are constructed, and for other details relative to their economy.

**EPHEDRA** (Linnæus). A curious genus of plants

belonging to the natural order *Conifera*. Two of them are hardy European dwarf bushes, the other is a climber from Barbary. They are propagated by layers or suckers.

EPHEMERA (Linnæus.) A genus of neuropterous insects, belonging to the section *Subulicornes* of Latreille, and forming the type of the family *Ephemeridae*, distinguished by the entirely membranous and almost obliterated structure of the mouth, the parts of which are very indistinct, the five jointed tarsi, the small size of the lower wings, which are even sometimes entirely wanting, and the slender threadlike appendages with which the tail is terminated.

The name of this genus has been given in consequence of the very short duration of the life of the insect when arrived at the perfect state, it is derived from the Greek, and signifies living only through a day. The insects are the may-flies of anglers, whose beautiful motions in the blaze of the evening sun, alternately rising and falling, cannot have failed to have attracted the notice of every observer of nature. The body is soft, long, and slender. The antennæ are very short and three jointed, the wings are generally carried either perpendicularly, or slightly inclined. The legs are long and slender, without bristles, the anterior pair being the longest, inserted close to the head, and stretched out in front of the body. The perfect insects generally appear in swarms about sunset, in fine summer or autumn evenings, along the margins of streams, lakes, &c., and occasionally in such numbers, that the ground is shortly afterwards so completely covered with their dead bodies, that in certain districts they are collected in cart loads, and used as manure. One species, *Ephemera albipennis*, is remarkable for the whiteness of its wings, so that its swarms have all the appearance of a fall of snow. It appears to have been this species, the proceedings of which are detailed by Mr. A. H. Davis, in the Entomological Magazine, and whose account, as illustrative of a remarkable peculiarity in the economy of the insects of this family, we here insert:—"On a fine evening, towards the latter end of May, I was collecting in the neighbourhood of Brixton, near some ponds, when I was suddenly covered by a multitude of small species of ephemera. They settled on me, apparently from my being the most conspicuous object near, on which to undergo their final transformation. Their colour was of a dusky white and opaque. They retained their position, without moving, enabling me to observe beneath the glass the process by which these fragile creatures withdraw themselves from the comparatively cumbersome garment which envelopes their beautiful and aerial form. Immediately on settling, the wings were laid flat at right angles with the body, and the insect remained about half a minute in a state of repose. A slight motion then appeared about the basis of the wings, which gradually collapsed, and were drawn alongside the abdomen. At this moment the insect resembled a piece of dirty cotton-wool, with little form. The elevated portion of the thorax now distended, and then gave way longitudinally, exhibiting the bright brown thorax of the insect, which was rapidly followed by the head and anterior legs. After this effort, the insect rested a few seconds. The next discernible motion was in the two or three last segments of the abdomen, where the muscles were in violent agitation, evidently for

the purpose of extricating the fine setæ which adorn that part. The contractions continued upwards, and the wings, freed from their flimsy covering, were fully developed, and in an instant the delivered captive took its flight; the whole process strongly resembling the drawing off of a tight glove. The whole operation did not, in most cases, exceed three minutes; in some cases less. Scarcely an instant elapsed between the full development of the insect and its taking flight, so rapidly did they acquire consistency. In some few instances I observed them coupled, in which case they soon died. I made a dozen or so find their way into a phial; they instantly deposited their eggs, and died; one only, which I believe was a male, survived when I reached home, less than one hour after.

"The number of the insects was truly surprising, they covered every part of my apparel, and my face and hands were not exempt. On my arrival at home, my hat looked like a miller's, from being completely covered with exuvie. I had taken several of these insects during the evening, and had put them into pill boxes; almost all, however, were immature, and died without undergoing their metamorphosis, from which it would appear that light and a free atmosphere are essential to its accomplishment. The principal swarm, however, appeared about an hour before sunset, and enjoyed their hour's existence in one of the finest sunsets of this glorious summer."

The singular circumstance of these insects undergoing a shedding of the outer skin, after they have arrived at their winged state, is an apparent exception to the general rules of insect metamorphoses. It is, however, to be observed, that many insects appear, on bursting from the pupa state, to be enveloped in a delicate membrane, which is immediately burst and thrown off. This has been often observed by persons who rear lepidopterous insects, and it appears to us that this envelope of the ephemera is perfectly analogous to the pellicle of the moth, being however, from its former consistence, retained longer by the insect.

On arriving at the perfect state, the only operation which these insects have to perform is the propagation of their race, the imperfect and rudimental structure of the mouth preventing their taking any nourishment in this state. The female, immediately after impregnation, deposits her eggs in a mass in the water.

But although the may-fly lives only a very short time when it has attained the winged state, its existence in the larva and pupa states has been much longer, sometimes lasting even two or three years. During this period it resides in the water, often concealed during the day beneath stones or in holes, and sometimes in horizontal burrows divided internally into two canals, each having its own orifice. These burrows are always formed in clayey soils, covered by the water, which penetrates its cavities, and it has been supposed that it is upon this soil that the larva feeds. These larvæ differ from the perfect insect, not only by being destitute of wings, but in several other particulars. The antennæ are longer, the simple eyes are wanting, the mouth is provided with a pair of corneous jaw-like appendages, the abdomen is furnished on each side with a series of leaf-like plates, ordinarily disposed in pairs, at the base of which are a kind of false branchiæ or gills, upon which the tracheæ are laid out in a branching direction, and

which serve, not only as organs of respiration, but also of locomotion, being moved with facility. The tarsi have but a single claw. The extremity of the body is furnished with several short ciliated filaments. The pupa differs only from the larva in having rudiments of wing covers.

One of the species, which, from its abundance, has been termed *Ephemera vulgata*, is well known to the angler as a famous bait for the trout. It appears in May and June. Gilbert White says of it:—"June 10, 1771—Myriads of May flies appeared for the first time on the Alresford stream. The air was crowded with them, and the surface of the water covered. Large trouts sucked them in as they lay struggling on the surface of the stream, unable to rise until their wings were dried. This appearance reconciled me in some measure to the wonderful account that Scopoli gives of the quantities emerging from the rivers of Carniola. Their motions are very peculiar, up and down for many yards almost in a perpendicular line."

The number of species of this family ascertained to be inhabitants of this country is about fifty, the majority of which are as yet undescribed. They are divisible into generic sections, from the number of wings and caudal filaments, as follows:—

- Genus *Baetis*, Leach; filaments 2; wings 4. Type, *E. biloculata*, Linn.
- *Cloeon*, Leach; filaments 2; wings 2. Type, *E. diptera*, Linn.
- *Ephemera*, Linn.; filaments 3; wings 4. Type, *E. vulgata*, Linn.
- *Brachycercus*, Curt.; filaments 3; wings 2. Type, *E. brevicauda*, Fab.

We presume that the latter genus was intended to have been named *Macrocerus* (long-tailed), instead of *Brachycercus* (short-tailed), the tails in the typical species being exceedingly long. The largest species in the family is the *Ephemera Swammerdamiana*, being that whose transformations and anatomy were described by Swammerdam. It belongs to the genus *Baetis*, if indeed it be not the type of a distinct genus, as its large size seems to indicate. The largest British species of the family is the common may-fly described above.

**EPIDENDRUM** (Linnæus). A rather extensive and curious genus of plants, belonging to the natural order *Orchideæ*. Generic character: sepals free, spreading, labellum clawed, claw united to the tube of the column; the lip often three-lobed; pollen masses parallel. This genus, like all the rest of the order, are remarkable plants. One section of the epidendra has a kind of gouty stems, which are neither bulbs nor tubers. Another section is destitute of these swollen stems, and is more terrestrial than the others; some of which are epiphytes, living on the stems of trees, and when removed will preserve their vitality for a considerable time, and flourish suspended by a string without either earth or condensed water; hence they are called air plants.

**EPIGCEA** (Linnæus). A small creeping plant found in North America. It belongs to the tenth class of Linnæan botany, and to the natural order *Rhodoraceæ*. It is a hardy plant, and thrives well in our common borders.

**EPILOBIUM** (Linnæus). A genus of herbaceous plants, mostly perennials and natives of Europe. Class and order *Ocandria Monogynia*, and natural order *Onagrariceæ*. One of the most common is the willow

herb, often seen in shady places in hedge banks; nine others are natives of Britain.

**EPIPACTIS** (Richard). A genus of two orchideous plants, both natives of Britain, found in most woods and marshes. The *E. latifolia* was formerly called *Serapias latifolia* by Linnæus. They are admitted into the flower garden, where they thrive much better than many other wild orchises.

**EPIPHYLLUM** (Haworth). A genus of remarkably showy succulent plants separated from the genus *Cactus*. The flowers are icosandrious, and the plants belong to the natural order *Opuntiaceæ*. These plants are leafless; but the stems are dilated into leaf-like forms, and bear their splendid crimson flowers on the edges. They require a dry compost of a little loam and lime rubbish. The pots should be small and well drained, the plants needing but little water. They are readily struck from cuttings, which should be laid to dry for some time before they are planted.

**EPOMIS** (Bonelli). A handsome genus of coleopterous insects, belonging to the section *Pentamera*, family *Carabideæ*, and sub-family *Harpalides*, separated from *Chlanis*, to which it is very closely allied, by having the maxillary palpi terminated by an elongated hatchet-shaped joint, which is more dilated in the male than in the female; the lower lip has a bifid tooth in the centre. The type of this genus, of which there are but very few species, is the *Carabus circumscriptus*, two or three specimens of which existed in the old British collections.

**EQUISETACEÆ**—the horse-tail family. A natural order of acotyledonous or cellular plants, containing only one genus, but numerous species. This is a remarkable order of plants, having little affinity with any other tribes. It may be said to approach the *Cycadææ* and *Coniferaæ*. It resembles the fern-tribe in the want of the sexes and the presence of annular ducts without spiral vessels; while its germination is similar to that of mosses.

The essential characters of the order are: fructification terminal, in spikes or catkins, consisting of many-sided, shield-like scales, on the lower side of which are from four to seven involucre. These open longitudinally, and contain numerous round bodies having at their base four elastic club-shaped filaments, twisted spirally round them when dry, but expanding when moistened.

The plants belonging to the order are branched and leafless. Their stems are rigid, streaked, and hollow, and consist of several easily separated joints, each of which is surrounded by a membranous toothed sheath. Under the cuticle a quantity of siliceous or flinty matter is secreted. The branches are mostly in whorls.

The *Equisetaceæ* are widely dispersed over the globe, and generally grow in moist, marshy places. None of the species have as yet been found in New Holland. It would appear from the fossil remains discovered, that a great part of the original vegetation of our globe consisted of gigantic equisetums several yards long, much larger than any of our present species, which have generally weak stems, and seldom exceed three or four feet in height.

*Equisetum* is the only genus of the order. It includes numerous species, and some of which were formerly used medicinally as astringents and diuretics. From the quantity of flinty matter which they contain, they are used for various domestic purposes, such as polishing furniture. The flint in the living

plants amounts sometimes to thirteen per cent., and the ashes of the plants have been found to contain half their weight of that mineral.

*Equisetum hyemale*, (rough horse-tail), contains so much silex or flint, that its vegetable matter has been removed, and yet its form has been retained. It is used for the polishing of hard woods, brass, ivory, &c., and may be made to act as a file. In Northumberland, the dairy-maids use it to scour and clean their milk-pails. The plant is imported largely from Holland under the name of Dutch rushes.

On subjecting a portion of the cuticle of this plant to the analysis of polarised light under a high magnifying power, Sir David Brewster detected a beautiful arrangement of the siliceous particles, which are distributed in two lines parallel to the axis of the stems, and extending over the whole surface. In general the particles form straight lines, but sometimes they are grouped in oval forms, and connected together like the beads of a necklace. Many of the particles do not exceed the five-hundredth part of an inch in diameter. From the observations which he made, Sir David Brewster concludes, that the crystalline portions of silex are not foreign substances of accidental occurrence, but are integral parts of the plant itself, and probably perform some important function in the processes of vegetable life.

The fronds of *Equisetum arvense* are said to be hurtful to such animals as feed on them in autumn. *Equisetum fluviatile* was eaten by the common people among the Romans. It is said to be eaten by reindeer, and is used in some countries as food for cattle.

The seeds of the *Equisetums* possess hygrometrical properties: when exposed first to a dry and then to a moist atmosphere, they move about in various directions, according to the lengthening or shortening of the thread-like processes which are attached to them.

**ERANTHEMUM** (R. Brown). A genus of ornamental under-shrubs, chiefly tropical. Linnæan class and order *Diandria Monogynia*, and natural order *Acanthaceæ*. Generic character: calyx of four equal parts; corolla salver-shaped, limb five-cleft, nearly equal; stamens four, two of which are abortive, two fertile ones protruding. This is a free flowering genus in our stoves, thrives in a light rich soil, and is easily increased by cuttings.

**ERANTHUS** (Salisbury). This is the *Helleborus hyemalis* of Linnæus, and remarkable as being one of the first flowering plants of the early spring, preceding both the snowdrop and crocus. It is a polyandrous plant, and belongs to the natural order *Ranunculaceæ*. It is the winter aconite of English authors.

**EREMURUS** (Bieberstein). A genus included in the natural order *Asphodelaceæ*, and called *Asphodelus Altaicus* by Pallas. It is a herbaceous perennial, indigenous to Siberia, and has a place in our flower borders.

**ERIA** (Lindley). An orchideous genus, thought to be a *Dendrobium* by Dr. Hooker, but made a separate genus by Dr. Lindley. It receives its name from the extreme woolliness of the flower. Grown in turfy moor earth, and propagated by dividing the root.

**ERIANTHUS** (Michaux). A genus of gigantic grass, native of North America. It was supposed to be a species of *Saccharum* by Persoon, but Michaux's name is adopted.

**ERICA** (Linnæus). Heath. One of the most numerous families occurring in the vegetable kingdom.

Five hundred and forty-three species are named in published lists, besides numerous varieties. See **ERICÆÆ**.

**ERICÆÆ**, or **ERICINÆÆ**. The Heath Tribe. A natural order of monopetalous dicotyledonous plants, containing nearly thirty genera, and upwards of nine hundred known species. The order is allied to *Vaccinula* and *Campamilaceæ*, from both of which it differs in its superior ovary. It also bears an affinity to *Epacrideæ* and *Pyrolaceæ*, but is distinguished from the former by the structure of its anthers, and from the latter by its general habit, and the structure of its seeds.

Its essential botanical characters are, calyx persistent, inferior, four or five cleft; corolla hypogynous, four or five cleft, withering; stamens definite, equal in number to the segments of the corolla, or twice as many, inserted at the base of the calyx of the corolla; anthers two-celled, the cells hard and dry, separated either at the apex or base, where they are furnished with an appendix, and usually opening by pores; ovary free, surrounded at the base by a disk or by scales; one straight style, and a single undivided or toothed stigma; fruit capsular, many celled, with central placentas; seeds indefinite, minute.

The plants belonging to this order are shrubs, or under-shrubs, with evergreen, rigid, entire leaves without stipules. They cover immense tracts of country at the Cape of Good Hope, where upwards of three hundred separate species are found. The common heaths, or heather, form a considerable portion of the vegetation of large districts in England and Scotland. Heaths abound also in many parts of Europe, as well as in North and South America, both within and without the tropics. They are not common in Northern Asia or India, and in Australia they are scarcely known, their place being supplied by plants belonging to the order *Epacrideæ*.

In general the heaths possess bitter, astringent, and diuretic properties. The chief genera of the order are *Erica*, *Caluma*, *Andromeda*, *Ledum*, *Rhododendron*, *Azalea*, *Arbutus*, *Menziesia*, *Kalmia*, and *Gaultheria*.

Of the genus *Erica*, or true heath, there are five species indigenous in Britain: *Erica tetralix*, cross-leaved heath; *Erica cinerea*, five-leaved heath; *Erica Mediterranea*, *vagans*, and *ciliaris*.

The two first species, along with common ling, abound in all our moors, and are the badges of the clans of Mac Donald and Mac Alister. From the five-leaved heath the Picts used to make a delicious and wholesome liquor. In the following lines the poet alludes to this ancient practice, when he addresses this heath as,

Sweet, modest flower, in lonely deserts dun,  
Retiring still for converse with the sun,  
Whose sweets invite the soaring lark to stoop,  
And from thy cells the honeyed dew-bells scoop!  
Though unobtrusive all thy beauties shine,  
Yet boast, thou rival of the purpling vine!  
For once thy manantling juice was seen to laugh  
In peary cups, which monarchs loved to quaff;  
And frequent wake the wild inspired lay,  
On Teviot's hills, beneath the Pictish sway.

At the end of the last century, this tribe of plants consisted of three or four British shrubs, and a single Spanish one, but when the Cape of Good Hope fell into the hands of the British, an amazing number of species were immediately discovered. At the present day, the species, and the varieties produced by

cultivation, are almost endless. All the species are remarkable for their beauty, their elegance, or the fantastic forms which they assume, and some are prized for their perfume. The cultivation of them is attended with a considerable degree of difficulty, but they have been reared with great success in Britain. They are propagated by cuttings and seeds, which are planted in a peat soil, having a considerable mixture of sand. They do not require a warm climate in winter; it is sufficient if they are protected from frost. A great deal of light and air, and a regular supply of water, are necessary for their vigorous growth.

*Calluna vulgaris*, common heather or ling, is abundant on all the moors in this country. In the Highlands the plant is put to many important uses. It is extensively used for thatching cottages, and for making brooms. The Highlanders frequently make their beds with it, laying the root downwards and the top upwards. It supplies materials for fuel, and for making ropes, and is employed also for dyeing and tanning. It forms an excellent edging for garden plots, and bears clipping well. From its flowers bees extract a large quantity of honey, which, although of a dark colour, is remarkably wholesome and nutritious. Heather affords shelter to many birds, and its seeds form the principal food of grouse. For this purpose the seed vessel is so constructed that the seeds are preserved for a year, or longer.

*Arbutus*, or *Arctostaphylos uva ursi*, red bearberry or whortleberry, is an evergreen trailing shrub, abundant in the Highlands of Scotland, as well as in the north of England and Ireland. It bears small red, austere, and mealy berries, which are much eaten by moor fowls. The leaves have a styptic bitterish taste, and possess tonic, astringent, and diuretic properties. They are used medicinally in calculous or gravelly complaints, and in some diseases of the bladder. They have also been recommended in dysentery, and in consumption, combined with bark and opium. They may be administered either in powder or in infusion. The infusion made with cold water strikes a beautiful blue with persulphate of iron, in consequence of the large quantity of gallic acid which it contains. Besides this acid, the leaves contain tannin, resin, gum, extractive, woody matter, chlorophyll and water. When digested with alcohol they form a green tincture, which is rendered turbid by water, and when filtered passes through transparent and yellow, leaving a green resin on the filter. In some parts of Russia the plant is used for tanning.

*Arbutus*, or *Arctostaphylos alpina*, black bearberry, is another indigenous plant of this order, found on Ben Nevis, and many other Highland mountains. It is a trailing shrub, with elliptical leaves, which become in autumn of a fine red colour. The flowers are pale rose-coloured, and are succeeded by black berries, having something of the flavour of black currants.

*Arbutus unedo*, strawberry tree, the *arbutus* of Virgil, is a beautiful evergreen, indigenous about the lakes of Killarney in Ireland. In Crete and the Levant it becomes a bushy tree of very great size. From the beauty of its foliage this tree adds greatly to the claims of the lake scenery of Killarney. It is now a common ornament in our gardens, where it sometimes attains the height of eighteen or twenty feet. In the Botanic Garden of Edinburgh some specimens of the plant may be seen, which, under the care of Mr. Macnab, the able superintendent, have attained a size

and vigour scarcely equalled in this country. The tree bears pale greenish-white flowers, which are succeeded by red berries the size of cherries, and resembling strawberries in appearance. The fruit, which takes a year to ripen, is used as an article of food in Ireland and the south of France. When taken in too large a quantity it is said to act as a narcotic. In Corsica an agreeable wine is prepared from the berries. Several varieties of the plant are met with in nurseries, one with deep red flowers, called scarlet arbutus, another with double greenish flowers and narrow leaves, and a third with entire leaves.

*Arbutus andrachne*, oriental arbutus, and *Arbutus hybrida*, mule arbutus, have also been introduced into cultivation in Great Britain as ornamental shrubs.

*Andromeda* is another genus of this order, of which numerous species exist in America. *Andromeda polifolia* is found in marshy places in various parts of Britain. It is a small evergreen shrub, with rose-coloured drooping flowers, which are much concealed by the leaves. It sometimes receives the name of wild rosemary. *Andromeda hypnoides* is a moss-like plant which covers great tracts of ground in the Lapland alps, producing showy red flowers. The shoots of *Andromeda ovalifolia* have been known to poison goats in Nepal. From one of the species a volatile stimulating odoriferous oil is obtained which is used by the Japanese for the cure of rheumatism.

*Rhododendron* is a genus familiar to all on account of the beautiful species which are commonly cultivated in gardens. *Rhododendron chrysanthum*, yellow or golden flowered rhododendron, is a small plant which grows on the highest part of the snow covered mountains of Siberia, and is employed as an article of materia medica. Its leaves in powder or infusion, from their soporific and narcotic effects, are used as remedies in gout and rheumatism. In large doses they produce vomiting and delirium. From the effects produced by the infusion, it is called intoxicating tea in Russia. In this country the plant is scarcely ever employed now-a-days. *Rhododendron Ponticum* and *maximum* possess poisonous properties. *Rhododendron ferrugineum* and *hirsutum* are common on the high mountains of Switzerland, and terminate woody vegetation as we ascend. They furnish fuel to the shepherds, and grouse are said to eat them. *Rhododendron Caucasium* grows on the highest parts of Caucasus, near the limits of perpetual snow.

*Azalea procumbens* is found plentifully on the summits of most of the Scottish highland mountains, and abounds in the arctic regions. It is a low shrub, with a woody stem and crowded leafy branches. It has astringent properties. *Azalea Pontica* is a poisonous species. The honey collected by bees from the flowers of this plant is said to have poisoned some of the soldiers in the retreat of the ten thousand through Pontus.

*Kalmias* are beautiful peat-earth shrubs found chiefly in America. *Kalmia latifolia*, a native of Carolina and other parts of North America, grows on rocks hanging over rivulets, and on the sides of barren hills. It is one of the most elegant shrubs, and is prized both for the beauty of its foliage and the colour of its flowers. Unfortunately its poisonous qualities lessen in some degree the esteem which its beauty claims. An ointment made of the powdered leaves has been used in some obstinate cutaneous affections. The wood of the plant is hard, and well fitted for various domestic purposes. The brown powder which adheres

to the leaf-stalks of almost all the species of *Kalmia*, *Andromeda*, and *Rhododendron*, as well as that which surrounds their seeds, is used by the common people in the United States of America to excite sneezing. An infusion of *Gaulthiera procumbens* is used as tea in North America. It is stimulating, and somewhat anodyne. The berries are succulent and esculent, and are sometimes infused in brandy, which is then used like common bitters. *Ledum palustre* is astringent, and when used in the manufacture of beer renders it heady.

*Menziesia cœrulea* is a small shrub, found in a single station in Scotland, but frequent in America. It produces beautiful large purple-blue flowers, and is well worthy of a place in our gardens. Another species, *Menziesia polifolia*, is indigenous in Ireland, and is frequently cultivated.

This order, we have thus seen, is more distinguished for the beauty of the plants which it contains, than for the uses to which they are applied. Under it are included many of the most valuable green-house productions, and to it also is referred the heather-bell

That breathes the mountain air,

and which gives, in some degree, to the hills of Scotland their wild and romantic character.

**ERIGERON** (Linnaeus). A genus of annual, biennial, and perennial herbs, mostly found in Europe. Linnaean class and order *Syngenesia superflua*, and natural order *Compositæ*. Generic character: anthodium imbricated; receptacle naked; florets of the ray ligulate, and very narrow. Increased by seeds or dividing the roots, grows anywhere in flower borders.

**ERIGONUM** (Michaux). A genus of North American herbaceous perennials, belonging to the natural order *Polygonææ*. Generic character: flowers enclosed in a bell-shaped involucre; calyx bell-shaped, six-cleft, segments obtuse, interior ones somewhat smaller than the exterior; filaments like hairs, longer than the calyx; anthers ovate; style scarcely visible; stigma filiform; achenium three-sided and winged. These plants when cultivated thrive best in pots.

**ERINUS** (Linnaeus). Beautiful little alpine plants, belonging to *Didynamia angiospermia*, and to the natural order *Scrophularinææ*. Generic character: flowers somewhat spiked and bracteate; calyx regularly five-cleft; corolla inclining to salver-shaped, tube cylindrical, limb spreading, five-parted, segments inversely heart-shaped, sometimes emarginate; stamens short; style filiform, with beaded stigmas; capsule oblong, two-celled, two-valved, and many seeded. The *E. alpinus* grows readily on old walls, and increases itself readily by seeds. It is a favourite plant for rock-work. There are two or three greenhouse species.

**ERIOBOTRYA** (Lindley). A genus of Chinese fruit trees, belonging to the natural order *Rosacææ*. Generic character: calyx woolly, obtusely five-toothed; petals bearded; stamens equally joined to the calyx; styles five, filiform, and hairy; fruit from three to five celled, cells many seeded. The *E. Japonica* was introduced into this country about 1787, under the name of *Mespilus Japonica*, so called by Thunberg. It is said to be indigenous to Japan, but it is very common in China, and is the *Loquat* of Chinese fruiterers. It is a half hardy tree, and withstands frost with a slight covering.

**ERIOCEPHALUS** (Linnaeus). A genus of evergreen shrubs, introduced from the Cape of Good Hope. They belong to the natural order *Compositæ*. Greenhouse plants of easy culture, and propagated by cuttings.

**ERIODENDRON** (Decandolle). Tropical timber trees, formerly associated with the genus *Bombax*. The flowers are monadelphous, and the trees are placed in the natural order *Bombacææ*. Almost all the genera of this order are known by the capsules being lined with a kind of silky or cotton-like wool, which is put to various uses, but it has not tenacity enough for the fabrication of cloth. In our stoves these trees have necessarily a pigmy habit, and are propagated by cuttings.

**ERIOGASTER** (Germer). A genus of lepidopterous insects belonging to the section *Pomeridiana* of Stephens, family *Bombycidaæ*, and to the division with entire wings, and the palpi not advanced in front. The body in this genus is stout, and densely clothed with woolly hairs; the antennæ are slender, and attenuated at the extremity; the wings are somewhat transparent. The abdomen in the females is furnished with a mass of down. The type of the genus is the *Phalæna bombyx lanestris* (Linn.), a species known to collectors by the name of the small egger moth (so named from the resemblance of the cocoon to an egg), of rather common occurrence; the wings are of a dark reddish tinge, with an irregular toothed streak beyond the middle of the wing, and with a large basal and smaller central spot of a white colour. It varies in expanse from one inch and one-sixth to one inch and five-sixths. Like the genera *Cnethocampa* and *Clisiocampa* (which see), to which it is nearly related; this moth is gregarious in the caterpillar state, living in colonies under a common tent, from whence the inhabitants make nocturnal excursions in search of food, returning before morning by means of silken foot-roads parallel to the branches. The caterpillar is black and hairy, with two red hairy spots and three white streaks on each segment. It is found at the end of June feeding upon the sloe, birch, willow, whitethorn, and other trees. The moth appears at the end of February.

We have already, in our article *CHRYSLIS*, given an account of a curious circumstance which has been observed relative to the occasional duration of this insect for several years in the pupa state.

The cocoon is hard and of an egg-like appearance, somewhat resembling a pheasant's egg. Very little silk is employed in its composition, moreover it is spun with various little pin-holes, as if bored from without, the use of which has not been ascertained. It has, indeed, been suggested, that these apertures might be left as air-holes for the included chrysalis, "as the closer texture of the cocoon might, without this provision, prove fatal to the animal." Ins. Architect. p. 328.—This supposition can scarcely, however, be maintained, inasmuch as we find numerous cocoons of an equally firm texture, which are not furnished with such apertures. There is also another peculiarity which has been observed in this insect, and which is thus noticed by Mr. Haworth, in his *Lepidoptera Britannica*: "When an aurelian possesses a brood of this moth, he readily learns, on the arrival of the month of February, which of his pupæ will become winged that year. This always happens to by far the greater number; and its approach is denoted by the swelling of the larger belts of the

pupæ. Those which are intended to rest until another season do not swell until that season approaches. This swelling cannot be produced by heat, because all the pupæ, those which do not as well as those which do swell, are kept in an equal temperature, and experience the very same treatment. Perhaps," he adds, "they are endowed above by some differing principles which require the differing periods of one, two, and three seasons to repair and bring them to complete maturity, and render them capable of accomplishing the full intentions of their beneficent Creator." Without offering any opinion upon the cause of the prolongation of the chrysalis state, we may satisfactorily account for the swelling of the chrysalides, without attributing it to the acquisition of fresh matter, the swelling of the substance already there, or to the action of heat, by considering, that immediately before assuming the perfect state an increased quantity of air is imbibed by the insect, for the purpose of distending the exceedingly numerous ramifications of the newly developed respiratory organs. "This insect," further observes Mr. Haworth, "is probably of great service to many of our soft-billed birds, at a season when little and insufficient quantities of food are to be procured, especially in severe and rigorous winters, in which the ground remains a long time covered with snow, when this poor moth and some other species of lepidoptera (as soon as escaped from the pupa) stick torpid upon the trunks of trees, where these birds readily find and devour them\*, and thus escape from hunger at a time when worms or other terrestrial food are either difficult or impossible for them to procure; these birds, thus saved, are of incalculable service the following spring, in restraining within due limits the insect despoilers of the vegetable kingdom; during which they never fail to cheer us with their charming songs, and lessen the destructive numbers of caterpillars in our orchards and gardens, until in their turn they become the prey, the necessary prey, of some insidious weasel, or birds more powerful and rapacious than themselves; I repeat necessary prey, because they themselves would become too numerous if never destroyed, to the total extirpation of various insects, whose existence in the scale of things is as essential as their own to keep within appropriate bounds certain vegetables which otherwise would multiply to the total exclusion of other weaker and smaller, but equally necessary species; and so on, *ad infinitum*, until, at length, the head, and prince, and king, of all created beings, man himself, would feel the chasm, and experience inevitable woe."

**ERIOLENA** (Decandolle). An ornamental evergreen shrub, native of the East Indies, belonging to *Byttneriaceæ*. It is readily propagated by cuttings struck in peat.

**ERIOPHORUM** (Linnæus) is a genus of grass-like plants, belonging to the order *Cyperaceæ*, and is the cotton grass common on moors and bogs in many parts of Britain.

**ERIOSPERMUM** (Jacquin). A genus of bulbous rooted plants indigenous in Southern Africa. The flowers are hexandrous, and belong to the natural order *Asphodeleæ*. Generic character: corolla six-petaled, spreading; stamens inserted into the base

of the petals; filaments flatted and connivent; anthers double arrow-shaped; style triangular; stigma three lobed; capsule three-sided, three-celled, cells with several seeds. These bulbs are grown in loamy turf, moor earth, and sand mixed, and are increased by off-sets.

**ERIOSTEMON** (Smith). A genus of ornamental evergreen shrubs introduced from New Holland. The flowers are decandrous, and the plants are associated with the natural order *Rosaceæ*. They have some resemblance to *Diosma* or *Adenandra*, and are equally easy of culture in the greenhouse.

**ERISTALIS** (Meigen), a genus of dipterous insects, belonging to the section *Athericera*, and family *Syrphidæ*, having the thread of the antennæ pilose, and the external cell at the tip of the wing (situated near the angle at the extremity), with a deeply rounded notch at its outer side. The body is thick, the eyes pilose, the hind legs simple, and the third joint of the antennæ large and patelliform. The early states of these insects have been long known; they are described by Swammerdam and Reaumur. The larvæ are in the number of those which reside in the mud of stagnant water, and which have been termed rat-tailed larvæ, from the extraordinary elongation of the terminal segment of the abdomen, which is furnished at its extremity with an organ of respiration, which is easily brought into contact with the air at the surface, and at the same time permitting the larvæ, by the various degrees of extension of which it is capable, to retain its situation in various depths. Before passing to the pupa state the insect leaves the water, buries itself in the soft margin of the sides, the respiratory tube ceases its functions, the body contracts, the skin hardens, and becomes at length the covering of an inclosed pupa, in which the organs of respiration appear in the form of four small horns, placed at the front part of the body. The perfect insects delight in flowers, of which they suck the nectar, in bruised fruit, and in the sap which exudes from wounded trees of which they are not less fond. The females often deposit their eggs without ceasing their flight for this purpose; they suddenly drop themselves to the surface of the water, leaving an egg there, and as suddenly rise again. In this respect they agree with the dragon-flies. When settled upon leaves or other surfaces, the abdomen is alternately elevated and depressed from time to time. Their flight is very strong, and their movements, when on the wing, often very sudden: often they may be observed suspended as it were in the air, balancing themselves on their wings, which are kept in so rapid a motion as to be scarcely perceptible, darting off at the least approach of danger. In most of the species there are many generations in the course of the year. They are to be found in the winged state from the commencement of spring until the arrival of winter. There are about twenty British species of this genus, including the *Musca intricaria nemorum* and *Arbustorum* of Linnæus. The *Musca tenax* of Linnæus, and some other species, form a distinct section in the genus, having the bristle of the antennæ naked.

**ERITHALIS** (Linnæus). A genus of two species of trees, one is a fruit tree in Jamaica, the other deciduous ornamental of India. They are pentandrous, and belong to the order *Rubiaceæ*.

**ERODIUM** (Heretier). A genus of annual and perennial herbs, formerly classed with the geraniums. Linnæan class and order *Monadelphia Pentandria*, and

\* All insects, except lepidoptera in the winged state, conceal themselves during the time of severe frosts in places inaccessible to birds.

natural order *Geraniaceæ*. This division of the order have mostly regular flowers, and the seeds when united resemble a heron's beak; hence the generic name. They are mostly natives of Europe; three of them are British.

**ERODIUS** (Latreille), a genus of coleopterous insects, belonging to the section *Heteromera*, subsection *Melasoma*, and family *Pimelidæ*, having the body short, ovoid, gibbose above, with the thorax short and as broad behind as the base of the elytra, terminated posteriorly on each side by an acute angle; the prosternum is dilated behind into a plate resting upon the mesosternum. The genus comprises three subgenera, *Erodus*, *Zophosis*, and *Nyctelia*. In the first of these the two terminal joints of the antennæ are united so as to form a small mass, and the anterior tibiæ are furnished on the outer edge with a central and terminal spine. These insects, of which the species are very numerous, inhabit the sandy districts of the south of Europe, and the southern parts of Asia, and the north of Africa. The type is the *Erod-gibbus* of Fabricius: it inhabits Egypt.

**EROTYLUS** (Fabricius), an extensive genus of coleopterous insects, found only in South America, arranged by Latreille in the section *Tetramera*, but which possess so many characters, both as regards their habits and structure, in common with the *Engidæ*, that it appears much more natural to consider the structure of the tarsi as entitled only to a secondary importance. The three basal joints of the tarsi are dilated, cushioned beneath; the penultimate joint being bilobed. The antennæ are terminated by a dilated club composed of several joints, the lower jaws are armed with a corneous tooth, and the palpi terminated by a large transverse semilunar joint.—The species are adorned with numerous colours, in which yellow and red, with black spots and marks, are most prominent. From analogy with some allied British genera, we may consider these insects, which are of a moderate size, as inhabitants of fungi, boleti, &c. M. Duponchet has published a valuable monograph of the genus, all the species of which have been figured therein.

**ERPETION** (Sweet). A genus of plants separated from the genus *Viola* by the late Mr. Sweet. Class and order *Pentandria Monogynia*, and natural order *Violariææ*. Its species grow well in a warm border, and produce abundance of flowers. In sharp frost they require covering with a mat.

**ERVUM** (Linnaeus) is the generic name of the family of tares, so profusely scattered over Europe. They are all climbing annuals, some of them troublesome weeds among corn. Two of them, the *E. lens* and *E. ervilia*, are cultivated in the south of Europe and north of Africa as human food, and have so been from very remote antiquity. Lentils when boiled readily dissolve into a pulpy mass of a chocolate colour; and we learn that "it was for a mess of this 'red pottage' which Esau sold his birthright." In Egypt and Syria they are parched over the fire in pans, and commonly sold in shops, being considered by the natives the best food to be taken on long journeys. The use of lentils is very common on the continent, especially by the Roman Catholics during Lent. Lentils are also imported into London from Hamburg, for the use of cooks, who prize them as an ingredient in soups and sauces.—*Bar. Bot.*

Tares and vetches (*Vicia*) afford abundant green food for horses, sheep, and hogs; sometimes they are

made into hay, or reserved for seed, or for feeding pigeons. The winter vetch (*Vicia sativa*) is indispensable to the farmer; when sown along with a little rye in September, they stand the winter, and together are the first green food fit for use in the beginning of May; and then most acceptable as well as serviceable to horses which have been long kept on dry fodder.

**ERYCINA** (Lamarck). Only one species of this shell is described by Lamarck, and the equivocal character of these shells renders it very difficult to judge of their hinge. The shell is not quite so high as it is long; it is subtrigonal, regularly equivalve, inequilateral, slightly, or not at all gaping; the apices well marked, and inclining rather forward; the hinge sublunar; two unequal cardinal teeth, converging to the summit, and leaving a cavity between them; two lateral slightly distant teeth, lamellar and penetrating; the ligament interior, placed in the cavity; the valves exhibiting two rounded muscular impressions. The only recent species described inhabits the sands of New Holland, but several fossil are enumerated by De France, and others are figured by Deshayes in his work on the Fossil Shells found in the neighbourhood of Paris. This genus belongs to the eighth family *Conchaceæ*, first section, third order, *Lamelibranchiata*, third class *Acephalophora*.

**ERYNGIUM** (Linnaeus). A genus of perennial herbs found in every quarter of the world. Linnaean class and order *Pentandria Digynia*, and natural order *Umbelliferae*. Generic character: flowers in a head; receptacle chaffy; involucre rather spinous; petals inflexed; fruit chaffy or scaly, crowned with the calyx. Several individuals of this genus are admitted into the flower garden. Their coloured bractæ being their most striking feature. They affect light soil, and are increased by seeds, which ripen readily.

**ERYSIMUM** (Linnaeus). This genus is called in Britain hedge-mustard, from the acrid qualities with which it abounds. The species are mostly European, having tetradynamous flowers, consequently belonging to the natural order *Cruciferae*. It is propagated by seeds or cuttings.

**ERYTHRÆA** (Richard). A genus of annual, biennial, and perennial herbs, chiefly natives of Europe. They are ranked in the fifth class of sexual botany, and belong to the order *Gentianeæ* of the natural system. Generic character: calyx in five parts and five sided; corolla funnel-shaped, limb five-cleft; stamens joined to the tube of the corolla; anthers shed spirally; style short; stigmas two, roundish; capsule of two valves, bent inwards, and having a placenta. The British species called centaury, are met with on moors or dry pastures, and are considered most elegant native plants. When introduced into the flower garden, where they well deserve to be, the seed should be sown in the autumn to ensure their rising in the following spring.

**ERYTHRINA** (Linnaeus). A splendid genus of exotic trees, shrubs, and herbs, remarkable for their high coloured flowers, hence called coral trees. They belong to *Leguminosæ*. Generic character: calyx tubularly bell-shaped, truncated, sometimes with five or two teeth, or two lipped, often spathaceous; vexillum very long; keel of two petals; pod elongated and twisted. Some of the species require the heat of a stove; others stand well in the greenhouse; but the *E. cristagalli* and *E. laurifolia* will live in the open air if protected from the frost of winter; for though the stems die down, they shoot again from the

root, and flower beautifully in the summer. They may be propagated by cuttings. The seeds of *E. corallodendrum* are called Caffrarian peas by Barrow, probably from their being eaten as such by these people. The seeds of *E. Abyssinica* are said by Bruce to be called *karat* in Abyssinia, and there used as weights for gold, whence it is presumed we have our word carat.

**ESOX**—The pike. A genus of soft-finned fishes, with abdominal fins, in which the edge of the upper jaw is formed by the intermaxillary bones, or where it is not completely so formed, the maxillary bone is without teeth and concealed in the thickness of the lips; generally speaking, the fishes which compose this genus, or rather family, are voracious; but the three divisions of which it is made up are very unlike each other in most of their characters. These divisions are: *Esor*, the pike, properly so called; *Belone*, the gar-fish, and *Esoctus*, the flying fish; which last we shall notice under their English names, only remarking further here, that the pikes are inhabitants of the fresh waters; the other two divisions inhabit the salt; and the flying fishes, as their name imports, can make their way through the air for a short distance.

Pikes, properly so called, have small intermaxillary bones furnished with little pointed teeth in the middle of the upper jaw; the vomer, the palatal bones, the tongue, the pharynx, and even the rays of the gills, are set with teeth; and in the sides of the lower jaw there are large ragged teeth, which, in a fish of large size, are scarcely less than the canines of a small dog. No fresh water fish bites so powerfully as the pike, and hence it is looked upon as one which is peculiarly destructive to other fishes, though its own flesh is in considerable esteem for the table. The flesh is white and firm, but rather dry: there are three species, two of which have been found only or chiefly in the fresh waters of North America. One of these, *E. reticularis*, is marked all over with a net-work of brownish lines; and the other, *E. esor*, is sprinkled over with round blackish dots. The manners of these two species are but little known.

It is usually said that pike were unknown in the English rivers previous to the time of Henry VIII., and that when first introduced they were so rare, that a single pike sold for double the price of a house lamb. But there is little probability in this account, inasmuch as the pike is very generally distributed, not only through the cold and remote waters of the northern parts of the British islands, which nobody of course ever took the trouble of stocking with fish of any sort, but they are also distributed through the very coldest parts of Europe. Pike have been mentioned, as taken in Lapland, as much as eight feet in length; and in one of the slow running rivers of the Scotch highlands, we believe the Glass, we have heard of a six feet pike being taken; in the richer part of the country, they are not so large in size, but whether this be owing to less favourable pasture, or to more habitual fishing, has not been determined.

The general aspect of the pike is repulsive. It is a ragged, savage, and ugly looking fish, and a large portion of the middle of its body being nearly of an equal thickness, gives it a lumpy appearance. The head is very flat, the eyes small, and the irides golden yellow; the upper jaw is broad but shorter than the lower one, and the lower one turns upward at the point, where it is marked by minute punctures. The

teeth, as already mentioned, are very numerous, and are exceedingly sharp. The intermaxillary bones also allow a vast opening to the mouth, so that the pike can seize and swallow large prey. The body is considerably elongated, the back broad, and almost square when the fish is in good condition: at this time also, the colours on the back and sides are very fine, consisting of green mottled with bright yellow, and the gills are of a very bright red, indicating a vigorous degree of circulation. When the fish is out of season, these colours fade, the green turns to grey, and the gills are dull and darkish. The pectoral fins are situated immediately behind the gill openings, the ventral fins are about the middle of the body, and the dorsal and anal are far back, near the tail, which is very stout, with a broad and much forked fin. The whole shape of the fish evinces that the posterior part of the body is the grand impelling portion; and by this means the pike is enabled to rush straight upon its prey.

Those who treat of the manners of fishes record many anecdotes of the uncommon voracity of the pike. Dr. Plott says, "At lord Gower's canal, at Trentham, a pike seized the head of swan, while feeding under water, and gorged so much of it as killed them both; the servants observing the swan to remain motionless, went in the boat, and found both swan and pike dead." Gesner mentions a pike which seized the lips of a mule while drinking in the Rhone, and kept its hold so firmly that the mule carried it ashore. In the year 1798, as two gentlemen were angling in a pond, near Warnham, in Sussex, a pike, of only about seven pounds weight, seized a dog that was lapping the water, and was fairly landed, holding on by the dog; so also in the Blackwater, near Youghall, a yearling calf was seized by a pike, and succeeded in landing him; and there could be no greater proof of his voracity than this attempt to swallow a calf, when his stomach, upon being opened, was found to contain a large perch and a water rat, both entire.

The pike is indeed exceedingly voracious, and seems to be almost destitute of fear, for it has been known to contest for prey with the otter, which is an animal of very powerful bite. Pike, when sufficiently supplied with food, grow rapidly; they live long; and scarcely any foulness of the water will injure them; they often attain a very large size. In some of the Irish rivers, especially the Shannon, and the large lakes through which it passes, pike seventy pounds in weight, have sometimes been caught; and there are accounts of others of very large dimensions taken by trolling. One of the largest caught in this way was taken by colonel Thornton, in Scotland, in the year 1784. This fish was four feet nine inches long and eleven inches and a half deep in the body, and weighed within two ounces of fifty pounds. The colonel had him upon the line for an hour and a quarter before his strength was exhausted, and the tackle would not have held him if the colonel had not been in a boat, and thereby enabled to humour him by rowing.

The pike are fond of dull, shady, and unfrequented waters; but prefer a hard bottom to one covered with mud. In summer they are found among the aquatic plants near the shore of the pools; but in winter they retire into the depths, and hide themselves, if possible, under some projecting stone or irregularity at the bottom. Their spawning time is in March or April; a little sooner or later, according to the place and the season. For this purpose they

quit the large ponds and pools, and resort to the creeks and ditches, depositing their ova among the roots of the aquatic plants; ducks and other water birds are particularly fond of the spawn of the pike, and not only consume great quantities of it, but carry it off, adhering to their feathers, without being injured or having its vitality destroyed. By this means pikes often make their appearance in ponds where there were none before; and this fact, which was well established before any inquiry was made into its cause, was once the source of many conjectures.

Pennant mentions a curious method of taking pike in the fens of Lincolnshire. The fishermen use a basket open at the top and bottom; this they plunge down behind the stern of their punts or fenboats, and by poking with a stick ascertain whether there is a fish in it or not; if there is one, they immediately raise the basket, and throwing the fish into the punt, lower the basket to catch another.

These fish may be also taken with a noose and rod when they are basking in the shallow water, which they do on warm days, with the back at or even partially above the surface. They may also be shot, only the gun must be levelled lower than the fish, because of the refraction at the surface of the water, and also of the shot glancing there; but care must be taken not to insert the muzzle of the gun in the water, as the consequence would be the bursting of the barrel, to the great danger of the sportsman. There are many modes of capturing these fish; and their strength and voracity which render them too destructive in the fish pond, are recommendations in the eyes of the sportsman.

**ETHERIA** (Lamarck). This shell had probably escaped the notice of former conchologists, from its inhabiting the sea at a great depth, and from its being there attached by the lower valve to rocks, or other fixed objects. Lamarck, therefore, has the honour of having first given a description of it. In consequence of the irregularity of the shape, arising from the faculty the animal possesses of affixing its dwelling to the substance on which it was born, the general appearance of the shell resembles that of an oyster. It, however, is considered by Lamarck more nearly allied to the genus *Chama*, possessing, like the species of that genus, two separate lateral muscular impressions (notwithstanding which, subsequent authors have felt disposed to ally it to the *Margaritaceæ*), its having no tooth at the hinge, and the substance of the shell having a pearly appearance, and being lamellar, as in the oyster, clearly separates it from the genus *Chama*. These shells sometimes attain a considerable size, and are of an extremely variable form, as that depends, as before stated, upon the substance to which it becomes fixed at its birth. The interior of the valves is generally covered with very singular hollow globular irregularly-formed concretions, like small bladders, beneath the pearly coating. These may be only accidental, but it is so common that it appears characteristic. It has also a sub-cylindrical callosity attached to the base of the shell, which does not exist in a second species of this genus, also described by Lamarck. The general character of this shell may be described as irregular, inequivalve, adhering to the lower valve; apices short, and appearing as it were forced into the base of the valves; hinge without teeth, waved, subsinuous, unequal; two lateral and oblong muscular impressions; ligament external, winding, and partly

penetrating the shell. This genus is sub-divided into two species, those presenting an oblong callosity on the base of the valve and those which have none. In De Blainville's System of Malacology this genus belongs to the seventh family *Camacea*, third order *Lamellibranchiata*, third class *Acephalophora*.

**EUCALYPTUS** (Heretier). An extensive New Holland genus, many of them useful timber trees. They belong to *Icosandria*, and to the natural order *Myrtaceæ*. Generic character: calyx cut round in the middle, upper part open, and seated like a cup; stamens numerous, inserted in a ring within the cup; filaments like hair; anthers roundish; style simple; capsule four-celled, and many seeded. The first of these plants appeared in European collections about 1774, and many have been received since. They are greenhouse and conservatory plants, having fine foliage, and flower occasionally. They are propagated by cuttings, but not readily.

**EUCERA** (Latreille), a genus of hymenopterous insects, belonging to the section *Aculeata*, family *Apidae*, and subfamily *Scopulipedes*. The wings are furnished with two complete submarginal cells, the antennæ of the males are nearly as long as the body, and the two lateral divisions of the lower lip are filiform, and as long as the labial palpi. The antennæ of the males likewise exhibit another peculiarity; the last ten joints appearing, when placed under a powerful magnifier, to be composed of innumerable hexagons, similar to those of which the eyes of insects consist. These insects fly about sunny banks, the female making her cells at the bottom of cylindrical burrows formed in such situations. These cells are placed two or three inches below the surface of the ground, they are very smooth within, and of an oval form; in each of them the female places an egg with a sufficient supply of pollen paste for the future larva, which resembles that of the common bee, and which undergoes all its transformations in the cell in which it is born. The entrance of each cell is closed by a covering of earth. It is chiefly from labiate plants that the females collect the honey which they employ. The common species found in this country, and which appears early in spring, especially frequents *Ajuga reptans*, and *Glechoma hederacea*. There are but few species of this genus, of which the type is the *Apis longicornis* of Linnæus. This insect is about half an inch long; the thorax and basal joints of the abdomen are clothed with reddish hairs; the remainder of the abdomen blackish, and the nose yellow.

**EUCLEA** (Linnæus). A genus of two evergreen shrubs, natives of the Cape of Good Hope, belonging to the natural order *Euphorbiaceæ*. They thrive well under ordinary greenhouse treatment.

**EUCOMIS** (Heretier). A family of bulbous plants, introduced from the Cape. They belong to the sixth class, and first order of Linnæus, and to the natural order *Asphodeleæ*. Generic character: corolla wheel-shaped, regular, six-parted; filaments dilated at the base, partly united, anthers oval; style awl-shaped; stigma simple, capsule three-celled, many-seeded. These plants flower annually, and are more remarkable for their mode of flowering than for either the size or colour of the flowers.

**EUGENIA** (Linnæus). A fine genus of fruit and ornamental evergreen trees, natives of the warmer parts of the world. Linnæan class and order *Icosandria Monogynia*, and natural order *Rubiaceæ*. Generic character: calyx persisting, tube oblong,

limb in four parts; petals four, inserted into the throat of the calyx; stamens springing from a ring on the calyx: filaments awl-shaped, erect; anthers roundish; style simple, filiform; stigma obtuse; germen two-celled; berry one-celled. Several species of the *Eugenia* yield fine fragrant fruit, and are plentiful in the market of Malacca and other towns in the eastern islands of India.

**EUGLOSSA** (Latreille). A genus of beautiful bees inhabiting South America, having the parts of the mouth elongated into a proboscis, as long or longer than the body, the labial palpi are terminated in a point composed of the two last joints. Their economy is not known. Some of them are, however, supposed to be parasitic upon other bees.

**EULOPHIA** (R. Brown). A genus belonging to the *Orchideæ*; chiefly natives of Africa. There are eight species in the books, and have been all introduced into our collections within these last ten or twelve years. Two fine species from Sierra Leone require to be kept in the stove; the others do well in the greenhouse.

**EULOPHUS** (Geoffroy). A genus of minute but highly beautiful hymenopterous insects, belonging to the section *Terebrantia*, family *Pupivora*, Latreille, and family *Chalcidæ*, distinguished by having the tarsi composed of only four joints, and the antennæ of not more than eight or nine. In the males these organs are beautifully branched, the branches being long, and arising from the upper side. The *Ichneumon pectinicornis*, Linnæus, is the type. It is of a black colour and very minute. Geoffroy observed the economy of one of the species, which is parasitic in the body of the caterpillar of some nocturnal moth (*Noctua*), out of which, when arrived at the full size, numerous larvæ of the *Eulophus* burst forth, arranging themselves upon the leaf in a circle round the insect which they had thus destroyed. Here they assumed the pupa state, and shortly afterwards appeared in the winged form, being of a fine green colour, with the antennæ straw-coloured at the base. Several other species have been observed, whose economy differs somewhat from that of the preceding.

**EUMENES** (Fabricius). A genus of solitary wasps (*Vespidæ*), remarkable for the very narrow form of the basal segment of the abdomen, which is long and often pear-shaped, the lower lip is divided at its extremity into three lobes, glandular at the tips, the central one being the largest, heart-shaped, and notched at the extremity. The females, unlike those of the common gregarious wasp, separately construct their nests upon the twigs of plants, especially upon heaths with a very fine kind of earth. The nest is spherical, and, according to Geoffroy, filled with honey. There are numerous exotic species, but one only has hitherto been found in this country, namely, the *Eumenes atricornis*, which is met with in Hampshire on heathy situations.

**EUMOLPUS** (Kugellan). A genus of coleopterous insects, belonging to the section *Tetramera*, and family *Chrysomelidæ*, differing from *Cryptoccephalus*, to which they are very nearly allied by having the terminal joints at the antennæ dilated; the body is very convex, and the maxillary palpi thickened at the tips. The majority of these insects inhabit tropical countries; they are for the most part exceedingly brilliant in their colours. We have already, in our article upon the *Chrysomelidæ*, given an account of the ravages committed by a small species of this

genus upon the vines in the wine countries of Europe. Vide ante, page 41.

**EUOMPHALE**. A fossil genus of shells established by Sowerby, and forming one species of the present arrangement of the genus *Solarium*.

**EUONYMUS** (Tournefort). Is the common spindle-tree of our hedges. There are sixteen exotic species from different parts of the world, already described; some of the latest from Nepal.

**EUPATORIUM** (Linnæus). An extensive genus of herbs, shrubs, and under-shrubs, mostly natives of America. This genus gives a title to a sub-order in the extensive natural order *Compositæ*.

**EUPHORIA** (Commeline). A genus of Chinese and East Indian cultivated fruit trees; one of which is called by the Chinese *Litchee*, and another *Longan*; both common in the markets of Canton. Class and order *Oetandria Monogynia*, and natural order *Sapindaceæ*. These fruits are sweet with a sub-acid flavour, and when the outer shell is dried, the pulp surrounding the seed shrinks from the shell and remains good for several months. In the dried state they are brought to this and other countries of Europe.

**EUPHRASIA** (Linnæus). *Euphrasia officinalis* is the eyebright of British botany; a common annual frequent on dry pastures. Class and order *Didynamia Angiosperma*, and natural order *Scrophularinæ*.

**EUPLECTUS** (Kirby). A genus of coleopterous insects, belonging to the minute family *Pselaphidæ* (see *BRAXIS*), having the body considerably elongated and depressed, the antennæ with the two basal joints thickened, and the maxillary palpi conical at the tips. The species are found in deep situations, on moss, &c., or flying in clear sunshine. There are about a dozen species, including the type *Pselaphus nanus* of Riechenbach.

**EURYALE** (Salisbury). A curious aquatic plant, a native of India, very much resembling the water-lily in the shape of the leaves, their manner of floating on the surface of the water, and in the mode of flowering; but the leaves are remarkably rough with tubercles and spines, and the flowers are by no means so conspicuous, or so beautiful. Class and order, *Polyandria Monogynia*, and natural order *Nymphaeiaceæ*. When cultivated in this country, the seeds are sown in large tubs of water, and placed in a hotbed.

**EURYLES** (Salisbury), a bulbous genus found at Amboyna, and other places in the East Indies. It is a hexandrious plant, and belongs to the natural order *Amaryllidæ*. It was described as a *Pancratium* by Linnæus and Ker, and a *Crinum* by Roxburgh.

**EUTAXIA** (R. Brown). A genus of two species of evergreen shrubs, natives of New Holland. The flowers are decandrious, and belong to the natural order *Leguminosæ*. Those plants require pruning or topping when young, to make them bushy, and are easily increased by cuttings.

**EUTERPE** (Gaertner.) A genus of palms, natives of the African islands, of Madagascar, &c. and South America. They were united to the *Areca* family by Jacquin and others.

**EVANIIDÆ**. A family of hymenopterous insects belonging to the section *Terebrantia*, and sub-family *Pupivora*, having the antennæ composed of thirteen or fourteen joints, the mandibles toothed, the wings veined, and the abdomen attached to the thorax close to the scutellum. The ovipositor is either not exerted, as in *Evania* and *Pelecinus*, or very long, as in *Fenus*, *Aulacus*, and *Megalyra*.

The typical genus has the antennæ elbowed, the abdomen very minute and compressed, and fixed to the posterior and upper part of the thorax. The species are of small size, and are stated to be parasitic upon the species of cock roaches. The type, *Evania appendigaster*, Linnæus, is attached to the *Blatta Orientalis*, and is therefore not considered by Mr. Stephens as an original inhabitant of this country.

EVENING FLOWER is the *Hesperantha radiata*, of Ker, a family of bulbs allied to *Ixia*, natives of the Cape of Good Hope. They require the same treatment as other Cape bulbs, that is, potted in light soil, and kept in a cold frame to flower.

EVERGREEN THORN is the *Crataegus pyracantha* of Persoon. A hardy ornamental shrub, very frequently planted on the walls of town houses, where its scarlet fruit are particularly showy in winter. The fruit are seldom seen in the country, being devoured by birds as soon as they are ripe.

EVERLASTING is a species of *Gnaphalium*, so called from the long duration of the flower after being cut and dried.

EVERLASTING PEA is the *Lathyrus sylvestris* of Linnæus. The broad leaved species is also called everlasting, and is often seen growing against the walls of the courts of town houses.

EVOLVULUS (Linnæus), a genus of climbing exotic annuals, having handsome flowers, for which they are sometimes cultivated in our stoves. They belong to the fifth class of Linnæus, and to the natural order *Convolvulaceæ*.

EXACUM (Linnæus), a genus of exotic annuals belonging to *Tetrandria Monogynia*, and to the natural order *Gentianeæ*.

EXCÆCARIA (Linnæus), a genus of hothouse plants, belonging to the natural order *Euphorbiaceæ*. They are treated like other plants of the order, and increased by cuttings struck in heat.

EXOCARPOS (Labillardiere), a genus of timber shrubby, and climbing evergreen plants, found in New Holland. Linnæan class and order, *Monœcia Pentandria*, and belonging to the natural order *Osyceidææ*. These plants do well with ordinary greenhouse management.

EXOSTEMMA (Richard). A genus of ornamental timber trees, natives of the West Indies. Class and order, *Pentandria Monogynia*, natural order *Rubiaceæ*. These plants were formerly arranged with *Cinchona*, but separated therefrom by Richard. They are stove plants, grown on loam and moor-earth, and propagated by cuttings.

FABA (Moench). This is the well-known common garden bean, called by Linnæus *Vicia Faba*, and thereby signifying the plant to be a species of vetch. It is now raised to the rank of a genus, but without congeners. The flowers are diadelphous, and of course the plant is ranged among the *Leguminosæ*.

The common bean is one of our most useful culinary vegetables; and as a field crop, of very great value as horse food. There is a vast number of varieties of this vegetable, as well for garden as for field purposes; nearly a score of each are named in seedsmen's catalogues.

The grand object of the gardener in the culture of beans is to have them ready for the table as early as possible: to have a regular supply throughout the season, and always in abundance. With this view he

should sow the first crops in the months of October, November, and December, either on a warm and sheltered spot, where they are intended to remain, or on seed-beds when they may be conveniently covered in severe weather; whence they are transplanted into drills in the open borders, or quarters of the garden, when the wintery weather is past.

For all these early sowings, the mazagan variety is preferred, not only because it is one of the most delicate in flavour, but also because it is the hardiest of all the garden sorts. To have a regular supply, a pint of seed should be sowed every three weeks from the twentieth of October to March.

In January and February, and throughout the spring months, the larger sorts, beginning with long pods, should be put in at different times to allow the crops to succeed each other seriatim: the sowings to be continued till the of May, and even longer: for, if the white blossom or mazagan be sowed even so late as July, a favouring season may bring forth a late crop in the autumn.

In sowing these large seeds it should be observed that they require a firm seed-bed. The ground should be good, and specially prepared for them: but if this be done two months before the beans are put in, the seedlings will rise the stronger for it. But if sowed on newly digged or trenched ground, the bottom of the drills should be trodden hard as well as the earth with which they are covered. Even if dibbed into firmly consolidated ground, the plants rise with greater vigour.

Transplanting beans is practised by gardeners for two special reasons: first, as already observed, because the earliest sowings can be safely kept through the winter by being occasionally covered with glass or mats. Being sown thickly together in a frame, or on narrow beds in the open ground, they can, when necessarily, be easily covered with a mat or two, and, when the season permits, removed to their final stations. Another reason is, the check which the plants receive by the removal causes them to flower sooner, and at the same time makes them more abundantly fruitful. A seed-bed, moreover, requires but a small space: and it may happen that the ground intended for the crop, is occupied by other vegetables not yet to be cleared off, and which it may be advantageous or convenient to let remain, till the season for transplanting the beans arrive.

The bean, being a rank growing plant, requires a deep rich loamy or clayey soil, if a great crop be looked for; the stems, being high and heavy; require a firm hold of the ground, to prevent them being laid by the wind or rain; and this is the reason that, when planted on light garden soil, it should be well compacted, to allow the plants a good hold.

Beans are usually sowed or dibbed in drills, the dwarf-growing sorts at two feet, and the larger kinds at two and a half, or three feet intervals between the rows. The spaces from seed to seed varies with their size; two inches is enough for Mazagans, though Windsors require at least five-inch distances between. The fact is, the thinner they are sowed the better they grow, flower, and bear. During growth they should be kept free from weeds, and be earthed up when necessary.

Topping is an old and serviceable practice; if done in good time, that is, as soon as there is a sufficiency of blossom on the stem, it assists to swell the pods and seeds, and often prevents the attack of

FALCONS.

Ash coloured Falcon.

aphides, which invariably fix themselves on the tops.

Beans are cultivated on farms possessing a soil suitable for them. As before observed, it is only on naturally rich and heavy land that the culture of beans is profitable. In some districts wheat and beans are alternately raised on the same fields for many years together. The wheat stubble is dunged in the autumn, and then ploughed in; the surface becomes mellowed by the frosts of winter, and early in January is harrowed smooth, and the seed is immediately either drilled in by a machine, or dibbed by hand. The crop is kept clean by the hoe during summer, and cut and carried as early in the autumn as possible, to allow for ploughing, and sowing the seed.

Good crops are sometimes reaped from lighter descriptions of land, but these can only happen in consequence of the season being what is called 'a dripping one,' because, if dry, a light unprofitable return will certainly follow.

The best varieties of the common bean for garden culture are—the mazagan, early longpod, sword longpod, green or nonpareil longpod, Taylor's large Windsor, common ditto, and green ditto. Farmers' varieties are—small horse, the pigeon, the Heligoland, and mazagan. The larger sorts are also grown by farmers for the seedsmen.

**FABRICIA** (Gærtner). A genus of New Holland evergreen shrubs, belonging to the order *Myrtaceæ*. Generic character: calyx nearly superior, five-cleft; corolla of five clawless petals; stamens inserted on the throat of the calyx; filaments awl-shaped; anthers roundish; style simple; stigma capitate; capsule many-celled; seed small and winged. These plants are suitable for a lofty greenhouse or conservatory, and grow well on loam or moor earth. They are propagated by cuttings.

**FALCON** (*Falco*). A genus of *Accipitres*, *Raptores*, or birds of prey; and in some respects the most interesting of the whole order, and indeed of all the feathered race. They are inferior in size to the eagles and vultures, and also, feathers included, to some of the owls; but they are, of all birds, the most symmetrical in their forms, the most elegant in the style of their flight, and the most courageous and daring in the capture of their prey. It is indeed impossible to imagine a more beautiful adaptation than that of the falcon to the air and the air to the falcon. Light and graceful in their forms, firm in their plumage, beautifully adjusted in the relative proportions of their different structures, the falcons are perfect models. Not the eagle itself has a keener or more beautiful eye, though the eagle has to look out for prey which is lurking on the ground; and not any birds, even those which are most constantly on the wing, have their organs of flight so finely formed, and so firm in their texture, as the falcons. Nor are their organs of prehension and of preparing their food at all inferior. The beak of the falcon is not a large beak; neither are the claws of as large a size as they are in other birds of prey, which are less dashing, and even less powerful in the style of their preying. Vulgar belief is apt to associate power with those elements only which strike the first and unreflecting observation as being of the very highest order; and hence, a great beak and great claws, and the talons bent till they are semicircles, are the common notions of powerful armature in a bird of prey. But there cannot be a

greater mistake than this, or anything more calculated to give a false impression of that in which real power of action consists. Mere size is in itself a disadvantage; because matter, how much soever there may be of it, contains in itself no principle of action, and never moves unless it is moved by a mechanical or a vital impulse. Hence, in proportion as the beak of a bird is large and heavy, it requires the greater quantity of muscle to put it in action; and we know well, from comparing large and small animals of the same kind, that the large one, though its mass may give it great power for a short effort, is soon exhausted, and that the real power of endurance is in the small. So also in the claws of a bird of prey, curvature, beyond a certain degree, is a means of weakness, if the claw is to be an instrument for giving a death-stroke, and not a mere instrument of prehension. Thus, upon looking at the claws of the harpy eagle of America, and at those of one of the finest and boldest falcons of the northern mountains, one would be very apt to suppose that, from the size and curvature of the former, and also the size of the bird, it would be invincible; but if one of those large and lumbering catchers of fish were to meet in the free air of heaven with the white falcon of Iceland, and if the spirit of the falcon were up, for she seldom engages in mere strife, one stroke of her comparatively small claw would tumble the harpy to the earth. A very remarkable instance of the comparative feebleness of those crooked-clawed fishing birds of prey lately occurred at a collection in London, where a large and powerful osprey had been incautiously put into the same cage with a buzzard; and it had very nearly been made buzzard's food before the keepers could separate them. Some very characteristic species of the falcon will be found figured in the accompanying plate **FALCONS**.

In order, however, fully to appreciate the beauty of that adaptation, of which the falcons furnish so fine an instance, we must consider the medium in which they act, and the mode of their action in that medium. Now, though there are considerable differences of structure and of action among the different species or sub-divisions of falcons; yet they may be said to capture their prey in the free air, or to wound it there and send it down to the earth, more exclusively than any other birds of prey. In general flight the falcons do not perhaps rise so high as some of the eagles; and it is not necessary that they should; for while the eagle mounts up for the purpose of surveying a large horizon of the ground, the falcon scans a far extent of that air in which it floats; and its higher flight and more powerful wing, enable it to occupy a higher place in the sky, and take a wider range than any of the hawks, in which the wings are shorter, broader, and rounder than they are in the falcons, in order to suit a flight which consists of shorter stretches with more risings and descents.

From the rapidity of their flight, and the length of time which they can continue on the wing, falcons may be said to have command of the entire globe; though there are different species adapted to different localities, and it may be said that the more powerful and more splendid ones have their native localities in the cold and temperate latitudes. There are indeed few parts of the world without falcons of some description or other; but those of the warm latitudes are, generally speaking, of smaller size, less powerful wing, and far inferior celebrity to the noble hawks of the north, which was the appellation given to the falcons

in earlier times, when every lord rode out with his peregrine on his arm, and every lady with her merlin. It must be admitted that, in an economical point of view, hawking was by no means a profitable sport; but, in the days when it and similar pursuits occupied so much of the attention of our forefathers, the state of the country was very different to what it is at present. The accommodations of the mass of society were few; and the greater part of those, even of the most elevated and wealthy class, were not, generally speaking, of that delicate, expensive, and perishable character, which we find in modern times. The baronial castle was so massy, as to be good for several generations without any repair; and the same might be said of its homely and substantial furnishings. To strew the floor with rushes cost not more labour than the mere laying down of a carpet, to say nothing of the number of hands and length of time which must be employed and occupied in the manufacture of it, and of all the machinery necessary for the said manufacture. It was much the same in every thing else: the substantial implements and utensils of the people were all of a permanent and baronial character; and that they had been used by a long line of ancestors, gave them more merit in the eyes of the life occupants, than the first rate fashion of modern furnishings. At the same time there were few books, and equally few who either could read, or cared anything about the matter. We have seen charters granted by a Bishop, and signed in the Bishop's name by a lady, with the expressed declaration in the docket that the reason of this substitution was that the bishop could not write. When this was the case with the diocesan of an extensive, and far from a poor, province, it could not be supposed that the common file of even the lords of the soil could be *very* literary. Thus one can readily suppose that their time hung heavily upon their hands; and that, in order to escape from the ennui of their own ignorant society, they were glad to claim kindred with the beasts of the field and the fowls of the air in every possible way. It is true that their attention to these did not much promote the natural history of the creatures, in any one useful or rational sense of the term. But we must not blame them for this: there was little or no science of any kind in those days, and even down to our own times, the hunters and the hawkers have done very little towards increasing our rational knowledge of the animal kingdom. We believe we do them little injustice (and we have no wish to do them any), when we say, that all that they have done, unless where the love of natural history predominated over the love of mere sport, would not make above a page or two in the progressive annals of the science; while, in the more important and higher department of tracing the connection between any one animal and the general system of nature, we presume they could not with justice be found guilty of a single paragraph. Thus the use of falcons in sporting belongs to a former people, and though there are still a few who keep hawks, they may be regarded as being kept more from the vanity of ancestry than from any direct pleasure which the keepers have in the possession or use of them. No doubt there are a few, on the confines of the wilder districts, where there is still little to interest except the wild productions of those districts, who do keep falcons and fly them; but the very fact of those persons being found chiefly in the wild places, is of itself sufficient to show that *falconry* is a sport of a rude

and illiterate age of the world, and quite incongruous with the character of the present times. At the same time we are ready to admit that, among those who require these birds as a means of killing time as well as game, falconry is withal a splendid sport. The perfect training of birds which are, when in a state of nature, the most free and independent tenants of the sky, the grace and rapidity with which they perform their work, and all the circumstances of the sport, when exercised *bonâ fide* against animals truly wild, or left to the uncontrolled exercise of their natural powers and resources, has many charms about it,—not the least of which is that it carries one back to years which are long gone by. Now, however, it has only become an antiquary's tale, and, as such, it forms no portion of natural history. We have indeed falconers, who fly their "gentles" at pigeons and other birds which are let loose from a basket or trap; but the hunting or hawking of that which is previously in possession of the hunters, is a most ludicrous matter—an outrage upon antiquity, and puts one in mind of the covering of four brick walls and a flat roof over with stucco, in order to make a miserable counterfeit of a Gothic chapel, in which the supporters and the supported are made completely to change places. But to return to the falcons—

The general characters of the old genus *fulco*, which included all the diurnal birds of prey except the vultures, are these: the head is covered with feathers; beak hooked, and generally curved from its origin; at its base it has a coloured cere, more or less hairy; the under mandible obliquely rounded, and both the mandibles sometimes notched; nostrils lateral, rounded, or ovoid, pierced in the cere and open; the tarsi are covered with either scales or feathers; three toes before and one behind, the outermost one frequently connected by a membrane to the middle toe at its base; pointed and sharp claws, moveable, retractile, and much hooked. This numerous division of the diurnal birds of prey has been conveniently distributed into several sections. As well as the characters which we have just stated, they are distinguished by a projection over the eyebrows, which gives their eyes the appearance of being deeply seated in their orbits, and imparts a very different aspect to their physiognomy from that of the vultures. The first plumage differs very frequently in colour from that of the mature bird, which is not perfect till the third or fourth year, and even later, a circumstance which has betrayed many ornithologists into an erroneous multiplying of the species. In general the female is about one-third larger than the male, and has been providently endowed with superior strength, because it is necessary that she should both feed and protect her voracious offspring; whereas the smaller dimensions of the male are more adapted to the rapidity and loftiness of flight, and is accordingly more esteemed by falconers. Though they are all carnivorous, they seldom, except when pressed by hunger, which they are capable of enduring a long time, feed on carrion. They have a very acute sense of sight, and with surprising force pounce down on their prey with the greatest accuracy and promptitude; manifesting, however, very different degrees of courage in pursuit of their game. They are capable, owing to their great strength, of carrying birds or other animals, nearly as heavy as themselves, to a considerable distance, sometimes as much as forty miles or even more, for the nourishment of their

young. Many of the species eat fish, and others feed principally on the smaller birds, snakes, and reptiles. They never associate in flocks; and, except during the breeding season, even two of them are seldom seen together. Their nests or eyries are generally built in very lofty and inaccessible places; but there are a few that form them on the ground. Many of these remarks apply to the hawks with short and broad wings, as well as to the falcons properly so called; and indeed the habits of the one race run so much into the other on the confines, that it is not easy to draw the line of distinction between them. This is more especially the case in some of the foreign falcons, which are much less noble birds than those of the north; and some, which have many of the external characters, not only feed upon carrion, but occasionally upon crustacea, which is not the case with the more typical ones of Europe.

The peculiar characters of the true falcon are—the beak curved from its base, with a tooth, and sometimes two, on each side of the upper mandible near its point, and corresponding notches in the lower one. The point of the upper one is very sharp and much hooked, and that of the lower is rather sloping and convex, but acting with a powerful grinding motion against the concavity of the hook. The degree of toothiness in the mandibles does not bear any relation to the absolute power of the falcons; because the beak in them is an instrument for dressing their prey rather than for killing it; and therefore the smaller species, which prey upon little birds, and have many feathers to pull in order to obtain a small quantity of food, have the mandibles most complete in this respect, while some of the most powerful of the whole have the tooth comparatively blunt. In the wings of the true falcons the second quill is always the longest, though the first is very little inferior to it in length. These two have their shafts and webs remarkably firm; and the others, as far as the tenth, shortened gradually, so as to form a pointed wing.

Those pointed wings are not so good for straightforward flight in perfectly still air, as wings which are broader; and therefore, when there is no wind, and the falcon is on level flight, it always flies obliquely or curving; the same may be also observed in the swallow tribe, and indeed in all birds which have the wings much pointed. But this form of the wings constitutes, or at least constituted, one of the chief excellencies of the falcons as sporting birds. Such wings are of course not good for mounting the air, unless they have some resistance with which to contend; and therefore falcons “get the sky better” directly against the wind than in any other direction; and, as it is the reverse with birds at which falcons chiefly were flown, this gives the falcon great advantage in capturing those which are of powerful wing and doubling flight.

When a hawk or other bird of prey endeavours to gain the sky by flying with the wind, it is said to turn “down the wind;” and this was reckoned a very great imperfection, because the bird got on so slowly in this way, that the prey had time to escape before it could turn and take advantage of its “rush” from the upper air. The true falcon never turns down the wind in this way; and thus, when it is unable to come up with the prey in simple chase, and turns off to gain a sky power, it always turns to windward, and its ascent, if seen sideways, is much more nearly in a perpendicular direction than one would

expect. Indeed, any one who reflects on the matter will readily understand how the wind and the falcon, by being two forces acting at an angle to each other, must produce a resulting motion of the falcon, in the diagonal direction, and upon the well known principle of the composition of forces, and the resulting force in mechanics, send the bird much more rapidly, and much more directly upwards, than if it had to work its way wholly by the action of the wings. The falcon thus gains her elevation with comparatively little labour, and arrives at the same altitude with much less horizontal distance than if she had a side wind, and especially if she went down the wind, which would then carry her horizontally away from the prey, and render it exceedingly difficult for her to gain such a height, as that she would return upon it with any impetus, or indeed with any chance of seizing it. This is a very beautiful instance of mechanical action, and structural adaptation of the falcon to the wind; and we shall not admire it the less when we come to consider that the more powerful falcons chiefly inhabit those places of the earth and those descriptions of surface where the winds are never long at rest. The falcon is a mountaineer, not exactly a cliff bird like the golden eagle, but a careerer of moor and dell, where the differences of these are considerable, and where, what with one diversity of surface and what with another, there is generally a wind from some point to act as a lever in heaving up the falcon to her height in the sky, and that with the least possible horizontal deviation from that prey upon which she is to rush after she turns. In this part of her action she bears some resemblance to the eagles, though in general she strikes in the air, and not on the earth as the eagle does. After she turns, she remains poised for a few moments, her wings acting the while with great rapidity; and there is little doubt that this action of the wings tends to excite all the energies of the bird to their very utmost, as well as to enable her to take her aim with unerring certainty. The moment that she has by this means gained her excitement and her poise, the rush with which she descends resembles that of the lightning, and, when seen laterally, it absolutely dazzles the eye. In such a case, if the breeze is moderately fresh, and the falcon powerful, the capture of her prey is certain, be it almost what bird it may; for she now descends, in her oblique but arrowy path, by the combined energy of three forces—her own excited action, her gravitation, and the force of the wind. The prey seems to be well aware of this, for, though it may be a lapwing, or a pigeon, or any other bird which is “clever at its feathers,” and which has thrown her out at simple chase till she has abandoned that style of pursuit, it screams and appears powerless and vanquished, even while the falcon is yet so high as to appear no bigger than a lark; and after the scream one can hardly count moments till the prey is struck to the ground. In the whole action of animals of wild nature in the finding of their food, there is perhaps none equal in point of style and beauty of mechanical contrivance, and adaptation to this contrivance, as this rush of the falcon upon the wide moor, where prey and preyer are equally in their element in free nature, and in the full possession and practice of all their resources. We shall perhaps have to revert to it in the course of this article.

Among falcons, properly so called, Cuvier makes a distinction which is probably well founded; and that is, the distinction between falcons and jerfalcone.

The former have the beak more completely toothed than the latter ; but the latter are the more powerful birds, not inferior certainly in point of wing, were equally docile when trained for falconry, more hardy from being inhabitants of colder climates, and when genuine perhaps more esteemed. We shall now notice a few of the principal species, and, in the first place, we shall advert to the falcons properly so called, which are numerous. and then to the jersfalcons, which are comparatively few. We may remark, however, in passing, that it is very difficult to be correct with species in the case of falcons, more especially of those which are natives of foreign countries, and of which only a few specimens have been seen. There is hardly a European or even a British species which has not, when in different plumages, been described as more than one species ; and very generally the male, which is always about a third less in weight than the female, and differently coloured, has been regarded as an entirely different bird. In some respects the difference is correct ; for the female is generally, if not always, a bird of bolder character and a more noble preyer than the male. The falconers were well aware of this ; for, while every honour was associated with the name of the *falcon* or female, the *tersel* or male was an inglorious appellation. In their early plumages and before they acquired the grey, which is characteristic of the mature birds, the female was a *red* falcon and the male a *red* tersel, but these latter appellations were chiefly applied to mature birds of the species which we shall first describe.

THE PEREGRINE FALCON (*Falco peregrinus*) is the falcon *par excellence*, because, though perhaps not the most powerful, it was the most generally in use, and also one of the most elegant. The length of the female is about sixteen or seventeen inches, and the extent of the wings an inch or two more than three feet. The bill is bluish black, yellowish at the base ; gape and cere yellow. The whole upper parts of the plumage dusky black, with a cinereous dash ; the shafts of the feathers black, and the margins slightly edged with ferruginous brown ; the forehead pale ; the sides of the neck and back mixed with yellowish white ; a black patch behind the eye ; from the corner of the mouth a broad black streak pointing downwards ; chin ferruginous white ; the whole of the under parts the same, with a broad streak of dusky black down the shafts, less conspicuous on the throat and vent ; under and upper tail coverts barred with dusky and ferruginous white, the former dashed with cinereous ; quill feathers dusky black dashed with cinereous ; the inner webs with transverse oblong spots of ferruginous white ; the under coverts of the wings alternately barred with black and white. Tail dusky black, dashed with cinereous, with eight pale ferruginous bars, least conspicuous on the outer webs of the exterior feathers ; one of the bars constitutes the extremity. The bill and talons of this species are remarkably strong, the former being much hooked, and furnished with a tooth-like process on each side of the upper mandible, which enables it to cut and tear its prey with greater ease. The wings are very pointed, the second feather being the longest, the first not much inferior, and the tail short, so that the wings when closed reach very near the end. The legs short, strong, and pale yellow ; the toes long, and furnished with a projecting callus beneath at the second joint.

Though most abundant in the hilly parts of the temperate regions of the world, the peregrine falcon,

from the vigour of its flight, is occasionally seen in all parts of the world, at least of the eastern hemisphere ; and indeed the range from the middle of Europe to that of Africa is only a morning's flight for it. It is also as long-lived as it is fleet and discursive. One is mentioned as having been met with in Southern Africa, in the year 1793, wearing a gold collar dated 1610, and known at that time to have belonged to James I. ; though more than 180 years old, it was still in complete vigour.

Peregrine.

The peregrine falcon inhabits all the temperate and colder parts of Europe, ranging from Iceland to the islands of the Mediterranean, frequenting high and rocky mountains, and building its nest, about the end of February, in precipitous cliffs, with a southern aspect. The eggs are generally three or four in number, white and spotted with brown. It is rarely met with in champaign countries, and never in those of a marshy description. In Germany and France it abounds, is pretty common in Holland and England, but is seldom met with in Switzerland. There is scarcely any part of our coasts, from north to south, where the cliffs rise to three or four hundred feet, in which they are not found scattered in the breeding season, and from which they seldom retire, except as occasional migrants, or when the young are driven to seek for fresh quarters. The insulated rock on which the castle of Dumbarton stands has been particularly quoted for a breed of the peregrine falcon. The growth of the young is so rapid that in three months they are said to equal their parents in size. We may also remark that they are very courageous birds, darting suddenly, perpendicularly, and with great rapidity, on their prey, which principally consists of partridges, pheasants, quails, wood pigeons, &c., and the smaller quadrupeds. They also attack the kite, and compel it to relinquish its victim, but spare its life, as if in contempt of such a dastardly adversary. Various instances are recorded of their fleetness of flight ; thus, one that eloped from its master, in the county of Forfar, on the 24th of September, 1772, with four heavy bells at its feet, was killed on the morning of the 26th of the same month at Mostyn, in Flintshire. Another one, belonging to a Duke of Cleves, flew out of Westphalia into Prussia in one

day; and in the county of Norfolk one was known to make a flight at a woodcock, at nearly thirty miles in an hour. A still more remarkable example is that of a falcon which belonged to Henry IV., king of France, and which, having escaped from Fontainebleau, was found twenty-four miles after in Malta, the space thus traversed being not less than 1350 miles, and corresponding to a velocity of fifty miles an hour, supposing the bird to have been on wing the whole time. But, as these hawks never fly by night, such a rate of progress would amount to seventy miles an hour, supposing the day to have been at the longest, or to have lasted eighteen hours. It is probable, however, that he neither had so many hours of light in the twenty-four, nor that he was retaken the moment of his arrival, so that we may fairly conclude much less time was occupied in performing such a distant flight.

The wild gallinæ form the principal food of the peregrine falcon; and it strikes its prey occasionally with the beak as well as the talons, and on the ground as well as on the wing; but still its principal habit is that of a wing bird, and it often gives long and very vigorous chase. In their lowest descents they prey much upon partridges, though in their upper haunts they feed more upon the different species of grouse. When on partridge hunting they do not beat the air, as that would be the means of making the prey lie close and undiscovered in the herbage. The falcon keeps watch stationed on the top of a hillock, or a low branch of a tree; and when a covey of partridges rises it dashes across them, and endeavours to strike, which it often does with so much force as to kill the bird, and then doubling instantly, as if knowing what it had accomplished, it seizes it before it reaches the ground. When hunting for partridges its habits are peculiar; it does not beat the ground and descend upon them, but endeavours to raise them by flying close to the surface, in which case it makes a peculiar sound. It is by no means unlikely, however, that some of those low flights which have been attributed to the peregrine falcon are really those of the harriers or buzzards.

The gallinaceous birds, from their heavy and lumbering flight, are very easy prey when once on the wing, or when by any means they are once got sight of. They are not, however, the only prey of the peregrine; for it gives chase to ducks, pigeons, snipes, and other birds which have great command of themselves in the air; and it will continue in pursuit of these for a considerable number of miles, including doublings, in which last some of them are more dexterous than the falcon. On these chases the average rate of flight, including doublings, may be estimated at about sixty miles in the hour, or a mile each minute; but the forward rush of the falcon is probably twice as swift as this.

Of all the prey at which the peregrine flies, the heron appears to be the hardest to master. This arises in a great measure from the height at which the heron flies, and which renders it very difficult for the falcon to get the sky of him; and as falcons can do little or nothing to a bird above them, the heron is in perfect safety as long as he can keep uppermost. The heron too can ascend as rapidly on the wind as the falcon can do against it; and thus, as he makes much more distance on his ascent than if he were against the wind, the attempts of the falcon to gain the sky always throw her to a distance. Even when the falcon does get uppermost, her victory over the

heron is not so certain as that of most other birds. The heron has still a means of defence, which is not only good for self protection, but also somewhat perilous for the falcon. The immensely long neck of the heron is, during flight, either extended, if the flight is rapid, or folded back on the shoulders, if the bird is gliding on with easy wing; but the heron can also turn his neck so as to project his bayonet-like bill upward behind the wing, at the same time that he continues his flight. This answers two purposes; in the first place the head or neck of the heron are the parts at which the falcon strikes, because, though wounded in the wing and brought to the ground, the bill of the heron is so formidable, and he uses it with such dexterous rapidity, that he might defeat or even kill the falcon at close fight, though his wing were crippled. Now the doubling of these parts under the wing secures them from this danger, and the only part at which the falcon can strike with effect is the wing. But to strike at that is also dangerous, because from the position of the head the heron can see exactly the direction in which the falcon is coming, and so receive him on the point of his long and strong bill, as a soldier receives an enemy on the point of his bayonet. This difficulty which the falcon has in mastering the heron, made the hawking of that bird a very choice and even a royal sport in the days of hawking; and great pains were taken to preserve herons for this purpose. Indeed at close quarters, and when they are on an equality as to level, the heron is nearly a match for even the golden eagle itself, though in absolute power it is a comparatively feeble bird. There is an account given by Colonel Montagu, which is worth quoting in order to show how determinedly the heron will resist, even when subjected to that mutilation which sportsmen sometimes practice when they have made up their minds as to which of two contending animals shall certainly have the advantage. A female falcon of a year old, in the possession of Colonel Montagu, which had been taken before it could fly, and thus had had no experience in the killing of any thing but a small bird occasionally, was kept a whole day without food. At the expiration of this period, an old male heron was introduced into the apartment of which the falcon had free range; but the point of the heron's bill had been previously sawed off. "As soon as the heron was in motion, the falcon, who was also deprived of the means of flight, took post on a stool which was at one end of the room; and as the heron, regardless of his enemy, traversed the apartment, the falcon motionless kept her eyes fixed on her destined prey, till, after several turns round the room, she judged the heron was sufficiently near to effect her purpose, when she sprang at the head, intending to seize that part with her talons. In this, however, she failed, the stool not having given her sufficient elevation to reach the high erected head of the heron. This failure might probably have cost the falcon her life, had the bill of her antagonist been perfect; for she received a blow on her body that must otherwise have inflicted a severe, if not a mortal, wound from so pointed an instrument urged with such power. Baffled in this attempt, and having received a severe blow, it was conjectured no further attack would be made until the calls of hunger became more urgent. The falcon, however, soon regained her station, and it was not long before we perceived the heron, regardless of his foe, again pass very near, when the falcon, in a second attempt to seize

her prey as before, was equally foiled, and again received a severe check from the bill of the heron. Finding her efforts had failed for want of the advantages nature had assigned her, instinct directed the falcon to a box that stood on the opposite side of the room, which was somewhat higher. Here she again seemed to meditate another attack by watching every motion of the heron, who continued his rounds with a view to make his escape; and it was not long before an opportunity offered for falco to make an assault from her more elevated station: Here she had found an humble substitute for those powers with which nature had so amply furnished her, but of which she had been deprived, and at last succeeded in springing from her perch and seizing the unfortunate heron by the head and upper part of the neck with her talons, which instantly brought him to the ground. Now the unequal contest was soon determined; for in vain did the superior weight and strength of the heron drag and flounder with his enemy across the floor; in vain did he flap his unwieldy pinions to shake off the tyrant of the air; nor could even his gigantic legs force her from the bloody grasp; her work was short and certain; no efforts could compel her now to quit her deadly gripe; the powerful and only dreaded arms of her antagonist were secured, and, thus disarmed, he became a sure and easy prey. Scarcely was the gigantic bird prostrate on the ground, than death ensued; for in this noble race, destined for blood and slaughter, torture makes no part of its nature, but, like what we are told of the generous lion, exulting in death, but disdaining cruelty, in less than half a minute did the falcon tear out the gullet and windpipe of the heron, and regale on the head and neck.

It has often been said that the American bird of prey, popularly known in the United States as the duck hawk, is the same species as the peregrine falcon of Europe; but this seems doubtful, and indeed, with the exception of the osprey, it is questionable whether the same species of any bird of prey is found in the two continents; or if the same in origin, it is so much altered by climate and circumstances, as to form a variety at all events, if not a distinct species. Wilson says that the American bird, during the breeding season, retires to the gloomy recesses and swamps of the cedar forests, in the tall trees of which it constructs its nest, and rears its young secure from molestation. In these wilds, almost impenetrable to the foot of man, its screams are occasionally heard mingling with the hoarse tones of the heron and the hooting of the eagle owl. In this respect, and several others, the American duck hawk seems to differ from our peregrine falcon. The anecdotes related of the dexterity and prowess of this noble bird are innumerable; a writer, in a popular periodical, describes one pursuing a razor-bill, which, instead of assaulting as usual with the death pounce from the beak, he seized by the head with both claws, and made towards the land, his prisoner croaking, screaming, and struggling lustily, but being a heavy bird he so far overbalanced the aggressor that both descended fast towards the sea, when, just as they touched the water, the falcon let go his hold and ascended; the razor-bill as instantaneously diving below. The nest is generally placed upon the shelf of a rock, in which the bird lays four or five eggs of a reddish brown colour, a little blotched and variegated.

The peregrine falcon appears, in different indi-

viduals, and at different ages, of so many shades in the general colouring, that it has got, perhaps, more names than any other bird; and some of those single specimens which have been shot in different remote parts of the world, without any knowledge whatever of their manners, and which have been described as peregrine falcons, in all probability belonging to other genera.

The LANNER (*Falco lanarius*), is a species about which there are some doubts; though the descriptions of it are so precise, and have been so often repeated, that if it is a variety of the peregrine it differs greatly from the general appearance of that bird; though it must be admitted that the young are described as being very like those of the peregrine. The lanner is described as being rather larger than the peregrine, though smaller than the common buzzard. It is said to measure about twenty inches in length, and upwards of forty in the extent of the wings. According to Temminck, the closed wings reach to two-thirds the length of the tail; the middle toe is shorter than the tarsus; there is a black streak below the eye, which nearly or wholly disappears in the mature birds; the eggs are of a bluish colour, while those of the peregrine are yellow; and the first and second quills of the wings have their webs very narrow. It is said to occur in many parts of Europe, inhabiting Iceland and the Feroe Islands, Denmark, Sweden, the Tartarian deserts, and breeding in the vicinity of Astrachan. It is rarely met with in this island; but it is said to breed in Ireland. In Hungary it is pretty common, likewise in Poland, Russia, Austria, and Styria. In general they build their nests in hilly situations, either among rocks, or trees and brushwood. Though the lanner is a bold bird, and was formerly used in falconry, few particulars are recorded of its manners and habits.

The HOBBY (*Falco subbuteo*), is a very handsome little bird; very much resembling the peregrine falcon in shape and also in manners, though from its smaller size it subsists on humbler prey; and it is also more gaily coloured than its more powerful conqueror. The male hobby weighs about seven ounces; and is about twelve inches in length. The following are the general markings, but they are subject to differences, both from age and in the individual. The female is considerably larger than the male, weighing two or three ounces more; and, though there is a very considerable resemblance in the general plumage, the upper part is not so dark as in the male, and the light parts have less of the rust-coloured tint. The male has the bill blue; cere and orbits yellow; irides dusky; the head and upper parts of the body are of a dark dusky brown, almost black, dashed with ash-colour; the feathers margined with pale rufous brown; over the eye a light stroke; beneath the eye a black patch, extending in a point from the under mandible down each side of the throat; chin and throat white, extending round each side of the neck, and partly encircles it, but is broken behind by dusky streaks, and the white becomes more ferruginous as it inclines backward; the coverts of the wings like the back, but the feathers more slightly edged; quill-feathers dusky black, with oval ferruginous spots on the inner webs; the breast, belly, thighs, and under tail-coverts ferruginous, palest on the former, marked with dusky streaks; the tail like the back, barred on the inner webs with rust colour, except the middle feathers; tips whitish; legs yellow; claws black. The female

weighs about nine ounces, sometimes more, and very much resembles the male in plumage, but not so dark above, and the lighter parts beneath not so ferruginous. The wings of this bird are long and pointed, but do not reach to the end of the tail when closed; the second feather is longest. In the British islands the hobby may be regarded as a summer bird of passage, and it is the only British bird of prey which is so. It arrives in England about the beginning of April, and builds its nest shortly after upon some lofty tree; but it occasionally avails itself of the deserted nest of a resident bird that builds earlier, such as the crow or the magpie. The eggs are from two to four, which appear to be the average, greatest, and least number of the tribe. The young, which have more reddish orange or bronze on the back than the old birds, are fully feathered by the beginning of September, and in October the whole depart to warmer climes. This bird is a local one with us, and confined to England, seldom reaching northward of the central heights of the island. It is the contrast of the peregrine falcon in its favourite haunts, and is a bird of the cultivated land, as that is of the open wild. Indeed, it nestles in the wood, and frequently in the depth of the forest, if not very extensive; but it hunts in the fields, and though, as it comes with the summer birds of passage, one would be apt to suppose that it should feed on them, yet the lark is its favourite game, which, even at its greatest height, it assails in the sky. That height, indeed, is often so considerable, and the one bird so intent on capturing, and the other on escaping, that their manoeuvres can be seen better than most chases by birds of prey.

In this attempt to capture the lark, the hobby has to guard against two chances of escape in that bird. In the first place, if the lark can keep uppermost, so as to have complete command of the sky, the hobby can make nothing of it. But in order to get the better of this, it cannot venture upon the same bold ascent to which the more powerful falcons have recourse when in danger of being foiled by other game; for the hobby must take equal care that the lark does not get down to the ground, otherwise its escape would be equally certain. Every one must have noticed the beautiful style in which the lark comes down from the very top of the sky, by a path nearly as perpendicular as a stone does when it falls. This is a habit with the lark in the breeding season, and when there is nothing to alarm it. It may be heard on a fine spring day, showering down its enlivening song from the upper part of the sky, when itself is almost or altogether invisible, in consequence of its great elevation; but the upper sky is the place where sounds are heard to the greatest advantage, much better than they are at a quarter of the distance on the level surface. Thus the lark will hear the answer of its mate while that is altogether unheard by one attending only to the songster over head; and it will drop down like a falling stone, and run among the clods, repeating the conclusion of its stave in a softened and inviting tone. It would drop down from the hobby in the same manner, squat among the clods, and remain there so still and close that no eye could discern it, and as the hobby is just as much fitted for catching the lark as the lark is for escaping from the hobby, of course the hobby labours by every stratagem to prevent this. The chief aim of the hobby is to preserve exactly the same level with the lark, and to prevent it from getting either up or down; and if the lark were a bird of straight-for-

ward flight, the hobby would very soon capture it, both because it is a bird of more powerful wing, and because it is stimulated by hope while the lark is depressed with fear. But the lark wheels and doubles, and often succeeds in throwing its pursuer out. In time, however, it gets exhausted, and the hobby breaks across, catches it on the double, and the chase is at an end.

Notwithstanding its small size, this falcon does not confine itself to such game as larks, for it flies at young partridges, at snipes, and at many other species of birds, some of which are larger and more powerful than itself. But its great boldness, its rapidity of flight, and its power of continuance on the wing, give it many decided advantages; so that in the age of hawking the hobby was one of the pet falcons for small game; and used to afford what was considered as very beautiful sport.

The KESTREL (*Falco tinnunculus*). This is a very beautiful bird, about the same weight as the hobby, and having wings of nearly the same extent; but it is longer in body, much more slender, and feebler both in the beak and the talons. The female, as in all birds of prey, is larger and more finely formed than the male. She is reddish brown on the upper part, with arrow-head dusky spots on the head, back, and wing-coverts, and dusky bars on the tail, the last one broad, and the tips of the feathers margined with cream-colour. The quills, which are twenty-two in number, are dusky, relieved by white margins; the under part is reddish cream-colour, with indistinct dusky lines. The male, after the first year, has the head and tail grey, during which it very much resembles the female, the back brighter red, and with fewer spots, and the under part redder, with more distinct spots. The feathers on the chin are also more produced, and a black stripe proceeding from the gape, which gives the light grey above the eye the appearance of an eye-brow. The kestrel has a very peculiarly brilliant eye; the irides of which are rich brown, contrasting well with the dark stripe and pale feathers at the base of the bill and over the eye. The bill is very short, and the notch nearly obliterated, and upon the palate there are two rows of small teeth pointing downwards, and very much resembling those with which the tongues of beasts of prey are beset. The whole structure of the bird indicates that it is less adapted for pursuing winged game, tearing flesh, and pulling feathers, than those hawks which have long wings; and its habits correspond with these differences of structure. This species gets a variety of popular names, such as the stone-gall, the stannel, the wind-hover, and many others, all of which allude to the habit which it has of leaning gracefully on the air, with scarcely any motion of the wings at some periods, and with an exceedingly rapid motion at others. In these cases it is generally scrutinising the ground for nests of unfledged birds, and especially for mice; the latter of which form a principal article of its food. It is, indeed, altogether less daring in its predatory habits than any other of the falcons, and may perhaps, without much impropriety, be considered as forming a link between the falcons and the kites, and perhaps also, though to a less extent, between the diurnal and the twilight birds of prey; for it may often be seen near houses about dusk, catching the large beetles and moths, which operation it performs very dexterously with its foot, and contrives to convey them to its mouth without any pause in its flight.

There are considerable varieties of colour in some birds, which in shape and in habit very much resemble the kestrel as above described, and which, in fact, cannot perhaps be separated from it with much propriety. These inhabit the temperate parts of Europe and Asia, and also of North America, moving northward in the spring, and southward in the autumn. In the part of Europe north of the Baltic, the kestrel is a bird of passage, and seen only during the summer. It appears at the same time with the white wagtail, at the time when the crocus and the violet are in blossom; and it takes its departure in September, almost at the same time with the bird which accompanies it on its arrival. It usually constructs its nest in old ruins and towers, and sometimes in the woods, and will occasionally content itself with the deserted nest of a magpie or rook. Its own nest consists of sticks lined with wool or other soft materials. The eggs, which are four or five in number, are rather inferior in size to those of the sparrow-hawk, and are of a dirty white colour, blotched with rust-colour of various shades, and occasionally wholly covered with a deep rusty red. This species is a common inhabitant of our own country, especially about our rocky coasts, or in high or ruinous towers, proclaiming its presence by a loud tinkling and grating noise. It is frequently observed fixed, as it were, in clear weather, in one place, and fanning the air with its wings, being then very intent on its prey, such as field mice, moles, frogs, &c., which it darts upon like an arrow. It also preys on birds; and such is the determination and force with which it dashes along, either in pursuit of prey, or to escape from more powerful predatory birds, that it has been known to break through a window, and fall stunned in the middle of a room. When it preys on birds it pulls the feathers with great dexterity and neatness, but when mice are its food, it swallows them entire, and discharges the indigestible parts by the bill in castings or quids, in the same manner as the owls. It is far more familiar than most of the tribe; and very often pounces on the call birds used by bird-catchers, and getting entangled in their nets, loses its liberty.

The kestrel is very abundant in the Decan, or peninsular part of India; and exactly identical in both sexes with the kestrel of Europe; but Colonel Sykes, whose researches have thrown much light on the birds of India, mentions being in possession of a male bird exactly like the female of the kestrel in plumage and size, and consequently larger than the male kestrel: and, as this was shot from a party of five or six perched on the same tree, and without a male kestrel in company, he is induced to believe there is a distinct species, in which both sexes have the plumage of the female European kestrel. Remains of rats, mice, lizards, grasshoppers, and a bird, were found in the stomach of several specimens. In one stomach the remains of no less than four lizards were met with!

The MERLIN (*Falco æsalon*) is the smallest of all the British falcons, but it is one of the swiftest on the wing, the boldest in the chase, and the most easily tamed; and, therefore, in the days of falconry, it was in especial repute as a lady's hawk. The weight of the female merlin is only about six ounces, and the male is not more than five. There is considerable difference in colour between the female and young male, which resemble each other, and the male bird in full plumage. On this account they have often been described as different species, the female and young male, especially the latter, being called "stone

falcons." There is one circumstance in the habits of these birds, which, in so far, shows how likely it was for inattentive observers to fall into this mistake. The merlin, considered as a British bird, has very often been described as a migrant, appearing chiefly in the winter, whereas it is in reality a resident bird, and performs its migrations within the country. In the breeding season, it resorts to the lonely moors, where it constructs its nest in cliffs of rocks, heaps of stones, or bushes, according as one or the other may be most convenient. It resorts to those upland haunts about the same time when the summer migrants, or birds of summer movement, which winter abroad or in the lower and more fertile parts of the country, resort to the same places; and it quits these upland retreats at an advanced period of the season, following the other birds on their migration southward, though it does not appear that it quits the country along with those which winter in more tropical climates. In consequence of this movement, it is not met with in the southern or lower parts of the island during the summer; and, as there are but few persons who frequent the moors until the shooting season begins, the young merlins are then seen in their first plumage, and they are seen among stony places, which has of course got them the name of stone falcons. When the merlin comes to the margins of the cultivated land, it is one of the severest enemies of the partridge. Its eye is very keen, and its motions rapid; and thus it beats the fields with more success than even the larger hawks; and when it gets sight of a covey of partridges, it rarely departs without its bird. Notwithstanding its boldness and its power of wing, the merlin is one of the lowest-flighted falcons; and when on the cultivated lands, it is generally found skimming over the fields, or along the hedges, very close to the surface: and thus, as its prey is always below it, there is comparatively small chance of escape. In falconry the merlin was flown at ground birds, or at all events at low flighted ones, and was highly esteemed for the capture of these. Partridges have such instinctive alarm at this little falcon, that, in order to escape it, they will throng round a sportsman, and crouch at his feet.

It is probable that on the moors merlins follow the same habit; and capture on their nests many of those birds which breed in such places. Nor is it at all improbable that a sort of reprisal is made upon the merlins themselves, not in the capture of the old birds, but in the destruction of the eggs or the unfledged young, in the absence of the parent birds. From the nests that have been examined, there is reason to conclude that the broods of merlins, if all reared, would be much more numerous than those of almost any other falcon, the eggs being as many as six, while in most of the others they never exceed four, and are rarely so many. Merlins are, however, of much more rare occurrence than those whose eggs are more numerous; and thus there is some reason for believing that they must meet with casualties in the moors, in having their eggs destroyed by the hooded and carrion crows which frequent such places. The raven may also be an enemy to them; though the raven is not so much a plunderer of nests as the more feeble birds of the crow tribe; but the merlin itself would be no match for the raven; for, unless by one very lucky stroke, which it is difficult to get upon a bird so crafty as the raven, even the peregrine, or the goshawk, is not a match for this strong and determined bird, or at all events not more than a match.

The following are the most frequent colours of the male of this species : the bill of a bluish-lead colour, with the cere at the base greenish yellow, and the irides of the eyes dusky-brown ; the naked parts of the legs yellow, and the claws black ; the crown of the head is dusky brown, streaked with black down the shaft of each feather ; on the back of the head the feathers are white at the base, and tipped with rust-colour ; the middle of each feather black at the point ; the back, scapulars, rump, and wings cinereous lead-colour, each feather marked with a long slender line of black down the shaft ; greater quills black ; the inner webs marked with many oblong white spots ; those next the body are coloured like the back on the outer webs ; the inner webs spotted as the others ; the two first feathers are much indented towards the point of the inner web, as if cut with a pair of scissors ; the third feather rather exceeds the second in length, and is the longest ; the throat is nearly white ; breast, belly, sides and thighs rust-coloured, streaked with a dusky hue ; vent and under tail coverts pale rust-coloured ; the under wing coverts are rufous brown, with round white spots on each web ; tail like the back, crossed with six or seven bars of black ; the end black for almost an inch, slightly tipped with white ; legs yellow ; claws black.

The female merlin, and the male in the immature plumage, or that which has been designated the stone falcon, is different from the above ; and as the bird is one of considerable interest we shall quote the accurate description of one, an immature male, by Mr. Fuljambe :—" Length of the bird in question is about twelve inches ; bill lead-colour ; cere and irides yellow ; the feathers on the crown and back of the head brownish cinereous, with black shafts ; throat cream-colour, extending in a very narrow line over the eyes ; cheeks, back of the neck, and breast, rufous, with longitudinal spots of brown ; thighs pale rufous ; with a few very narrow lines of a brown colour pointing downwards ; the back scapulars and wing coverts bluish-cinereous, with black shafts to the feathers ; the prime quills have their inner webs marked with six large white spots, the base edged with white ; the outer web of the first feather is scalloped with white ; the second and third feather the longest ; the wings when closed reach within an inch of the end of the tail ; the tail is bluish-cinereous, with four black bars, that at the end an inch in breadth, the others narrower ; the tip white ; the under side of the tail white, barred as above ; the legs and toes yellow and slender."

The merlin is an exceedingly bold bird ; and when it is in the lower cultivated parts of the country, it does not hesitate to pursue little birds in gardens, and even to drive them into houses ; nor is this all, for it will sometimes make a dash at a bird in a cage, even though the cage be inside a house ; and there are instances of its having forfeited its liberty in consequence of its daring in this way. Even when captured full grown, the merlin is exceedingly docile and easily tamed ; and if duly fed, it is one of the most gentle creatures imaginable. Indeed it is a very general truth with regard to birds of prey, and the same holds good in the case of mammalia, that the boldest preys are the most easily tamed, and the most gentle when they are tamed. There is no more remarkable instance of this in birds, than the golden eagle and the brown owl. The owl, even though taken young, will snap with its beak, erect its feathers, and defend itself, or at all events endeavour to escape when-

ever it is approached ; but the eagle will so far enter into companionship as to follow its master, to conduct itself decorously in a dining-room, and even to amuse itself with those that are kind to it. The case of the dog is a parallel one in respect of mammalia. Of all animals of that class the dog in a state of nature is decidedly the most courageous ; and there is certainly no animal whatever which shows nearly the same degree of attachment as the dog does when domesticated. This is a very curious point in the physiology of animals, as it tends to prove, and actually proves, that if there is the requisite degree of energy in the animal, this energy may be turned either to good purpose or to bad, according to circumstances. In the whole of the irrational animals there is not, we believe, a single exception to this ; and it holds equally true in the case of man, there being no question that those who under favourable circumstances have displayed the most noble virtues, would, under circumstances of an adverse nature, have been the most daring in crime ; and there is just as little doubt that they who have disgraced human nature by the most desperate atrocities, would, under proper treatment, have been the best benefactors and the noblest ornaments of society. This fact embodies in it volumes of instruction, far more important than any mere description of a bird or of any other animal, or any detail of a fact, of what nature soever ; because it goes at once to the root of the question of the proper management of living nature, rational and irrational, so as to turn it to the greatest possible advantage. It does more than this : for herein the Almighty himself vindicates his own law, and establishes the truth of that benediction which he pronounced upon the new made world—" And God saw everything that he had made ; and, behold, it was very good."

If we could carry this short declaration along with us in all our researches in natural history, the advantages would be incalculable, and we should not, as we too frequently do, content ourselves with a mere description of the external appearances of animals, as if they were stocks or stones, neither should we wage against them a war of extermination on account of some fancied noxiousness or positive evil. " Behold, it is **VERY GOOD**" is the declaration of God himself, over everything animate or inanimate within the whole bounds of the creation ; and as this is an express, primary, and infallible declaration by Him to whom every atom of matter in every possible connection, throughout all space and during all time, is most intimately known, how shall we, how can we, how should we, escape the vengeance of His just displeasure, if we cast it behind us when we go forth to survey His works, and dare to set up, instead of this eternal and infallible standard, some paltry caprice of our own ?

Be what the creature will, it has been declared that it is "very good ;" and it is our duty, the very purpose for which we were made, to find out the proper answer to the question, "Good for *what* ?" Weeds overrun the garden, and choke those artificial plants which man has sown or planted for his use ; but "they are very good ;" they speak to the sluggard in language more forcible than all the laws which ever were enacted by human legislation ; and impress upon man that if he is to profit by the bounty of the earth, he must be diligent in performing those labours which are necessary for the security of this bounty. Insects of various kinds, and in different stages of their

multiform existence, are particularly annoying to mankind both within doors and without. But they also are "very good," and proclaim with voices louder than all the heralds upon earth, the necessity of cleanliness and care. In this manner we may go over the whole catalogue both of vegetable and of animal pests as they are *usually* called, and we should be able to show in the most satisfactory manner, that they are all equally deserving of that benediction which was bestowed upon them at the first.

There is in this much to reprove our ordinary conduct, and as much to teach us how we may, if we only will, listen to the reproof, and profit by the lesson. We are hereby reproved for presuming to set up our limited knowledge and experience as a standard of judgment; and we are taught that there is use and purpose in every created thing, however offensive or injurious it may appear, and that it is both our duty and our interest to find out this use. Indeed, to find out the uses of the productions of nature is the grand and only rational purpose of the study of natural history; and if we have not this in view, the study is an idle waste of time, no better than any other inoffensive dissipation; and the man who merely knows the external distinctions between plants in a *hortus siccus*, or animals in a museum, and can call them by all the different names which they have got in different countries and by different individuals, is really of no more use, and therefore has no more merit, than a man would have who should make a collection of all the different forms and kinds of buttons that ever were worn, and be able to tell the names of the makers and first wearers. One cannot help regretting that, while this perfectly insignificant counterfeit of natural history has occupied the attention of so many, the really important portion of the subject should have been so much neglected; and yet this has been undoubtedly the case in almost every department of nature. There are, for instance, innumerable collections of shells; but who can tell anything about the animals by which those shells were made and worn? So are there many collections of foreign birds; but who can tell anything about their manners? Even in this genus *falco*, the species with which we are familiar in this country have been confounded, and the characters misrepresented, down to a comparatively recent time; and when we come to those which are foreign to Europe, all that we can, except in a very few instances, present, is a mere catalogue of names, and a list of sizes and colours. Strange productions of nature are bought with great avidity as curiosities; but it would be a very good rule strictly to prohibit the introduction of any new plant or animal, unless its history came along with it. We require a character with a strange human being, and why should we not also require a character with a strange beast or a strange bird?

THE LITTLE KESTREL (*Falco tinnunculioides*) resembles the kestrel in its form and habits, but it is smaller in size. The upper part is rust colour, or russet; the top of the head and sides, and back of the head, ash-coloured; the coverts of the wings, the rump, and the tail-coverts, bluish-ash; the tip of the tail white, within which there is a large bar of black; the under part bright reddish, spotted and lined with black; the beak bluish, the feet yellow, and the claws white. This species inhabits rocky situations in the eastern part of Europe, but is rarely seen in

the western parts, and never, so far as we have any record, in the British islands.

RED-FOOTED FALCON (*Falco rufipes*). This is also a small species, and belongs to eastern Europe, but it appears to be rather more discursive than the one last mentioned, and we believe it has occurred in some parts of England as an exceedingly rare straggler. A specimen of this bird, which had been shot near Doncaster, was exhibited before the Committee of Science of the Zoological Society of London on the 27th of November, 1832. Its characters are: bluish ash on the upper part; breast and belly of the same colour, but paler; lower part of the belly, thighs, and under tail-coverts, bright reddish; beak black; irides and feet red; and claws yellow, with black tips. The length of the male bird is about ten inches and a half. The female is a little larger, and has the nape marked with reddish lines; the sides of the head and the throat bright reddish; the under part and the thighs reddish brown, with black markings. The plumage of the young is intermediate between that of the mature male and the mature female, but differs from both, and this has led to some little confusion. They have the cheeks and throat white; the breast and thighs spotted with brown; ten or twelve brown bars across the tail; and the feet yellow, and the claws whitish.

The species of which we have given some account include (as nearly as we can estimate) all the true falcons which are native and resident in Europe, not of course including the jerfalcons, which remain still to be noticed, and which are in some respects the most splendid birds of the genus. Of the foreign ones we can only give a mere list; and, from the long confusion of the European species, which are so generally known, and which were long so highly esteemed by the leading people of all countries, it would be too much to say that this list has many pretensions to correctness. Very likely the same species, of different sexes or ages, has been named and described as two; and very likely, also, there are many species hitherto unknown to us.

THE AMERICAN SPARROW HAWK (*Falco sparverius*). This is a bird of many names; it is the little falcon, the St. Domingo falcon, the New York merlin, the American merlin. The female is eleven inches long; and twenty-three inches from tip to tip of the expanded wings; the cere and legs yellow; bill blue, tipped with black; space round the eye greenish blue; iris deep dusky; head bluish ash; crown rufous; seven spots of black on a white ground surround the head; whole upper parts reddish bay, transversely streaked with black; primary and secondary quills black, spotted on their inner vanes with brownish white; whole lower parts yellowish white, marked with longitudinal streaks of brown, except the chin, vent, and femoral feathers, which are white; claws black. The male sparrow-hawk measures about ten inches, and is about twenty-one inches in the stretch of the wings; the whole upper parts of the head are of a fine slate blue, the shafts of the plumage being black, the crown excepted, which is marked with a bright reddish spot; the slate tapers to a point on each side of the neck; seven black spots surround the head, as in the female, on a reddish white ground, which also borders each sloping side of the blue; line over and under the eye and chin, white; femoral and vent feathers yellowish white; the rest of the lower

parts of the same tint, each feather being streaked down the centre with a long black drop, those on the breast slender, on the sides larger; upper part of the back and scapulars deep reddish bay, marked with ten transverse waves of black; whole wing-coverts, and ends of the secondaries, black, tipped with white, and spotted on their inner vanes with the same; lower part of the back, the rump, and the tail-coverts, plain bright bay; tail rounded, the two exterior feathers white, their inner vanes beautifully spotted with black; the next bright bay, with a broad band of black near its end, and tipped for half an inch with yellowish white; part of its lower exterior edge white, spotted with black, and its opposite interior edge touched with white; the whole of the others are very deep bay, with a single broad band of black near the end, and tipped with yellowish white; cere and legs yellow; orbits the same; bill light blue; iris of the eye dark, almost black; claws blue black.

This species is not confined to the United States, and indeed it is a native of the warm countries rather than the cold ones, being more abundant in the southern states of the American Union than in the northern, and being especially numerous in St. Domingo or Hayti, and not unknown on the continent of South America. In all probability, indeed, its colours and character may vary in different parts of the vast range of latitude over which it extends, so that it is possible that several of those species about the same size, which have been named as occurring in different parts of the American continent, are nothing more than climatal varieties of this one; and as it is one of the few foreign species of which the characters are tolerably well known, we shall quote from Wilson a short passage descriptive of its manners:—

It flies rather irregularly, occasionally suspending itself in the air, hovering over a particular spot for a minute or two, and then shooting off in another direction. It perches on the top of a dead tree or pole, in the middle of a field or meadow, and, as it alights, shuts its long wings so suddenly, that they seem instantly to disappear. It sits here in an almost perpendicular position, sometimes for an hour at a time, frequently jerking its tail, and reconnoitering the ground below, in every direction, for mice, lizards, &c. It approaches the farm-house, particularly in the morning, skulking about the farm-yard for mice or young chickens. It frequently plunges into a thicket after small birds, as if at random, but always with a particular, and generally with a fatal, aim. One day I observed a bird of this species perched on the highest top of a large poplar on the skirts of the wood, and was in the act of raising the gun to my eye, when he swept down with the rapidity of an arrow into a thicket of briars about thirty yards off, where I shot him dead, and, on coming up, found a small field-sparrow quivering in his grasp. Both our aims had been taken at the same instant, and, unfortunately for him, both were fatal. It is particularly fond of watching along hedge-rows and in orchards, where small birds usually resort. When grasshoppers are plenty, they form a considerable part of its food." Wilson adds a very characteristic instance of the delicacy of taste of this falcon in respect to its food:—"Though small snakes, mice, lizards, &c.," says he, "be favourite morsels with this active bird, yet we are not to suppose it altogether destitute of delicacy in feeding. It will seldom or never eat of

anything that it has not itself killed, and even that, if not (as epicures would term it) in good eating order, is sometimes rejected. A very respectable friend, through the medium of Mr. Bartram, informs me, that one morning he observed one of these hawks dart down on the ground, and seize a mouse, which he carried to a fence-post, where, after examining it for some time, he left it, and, a little while after, pounced upon another mouse, which he instantly carried off to his nest, in the hollow of a tree hard by. The gentleman, anxious to know why the hawk had rejected the first mouse, went up to it, and found it to be almost covered with lice, and greatly emaciated! Here was not only delicacy of taste, but sound and prudent reasoning. If I carry this to my nest, thought he, it will fill it with vermin, and hardly be worth eating.

"The blue jays have a particular antipathy to this bird, and frequently insult it by following and imitating its notes so exactly, as to deceive even those well acquainted with both. In return for all this abuse, the hawk contents himself with, now and then, feasting on the plumpest of his persecutors, who are, therefore, in perpetual dread of him; and yet, through some strange infatuation, or from fear that, if they lose sight of him, he may attack them unawares, the sparrow-hawk no sooner appears than the alarm is given, and the whole force of jays follow." This tendency which small birds have to crowd round and annoy their more powerful enemies, is a curious point in natural history, and one the rationale of which is not very easily understood; the more so, that it does not hold in the case of the very powerful birds of prey. Nobody we presume, has seen a flock of birds, either great or small, following and annoying the golden eagle, the jersalcoti, or even the peregrine. It is true that these prey less frequently upon little birds than the smaller hawks; and therefore they do not stand so directly in the character of enemies; but still, as was observed by Wilson, and is reported by American naturalists generally, the ospreys crowd round and annoy the white-headed eagle. The grand object seems to be, so to distract the attention of the enemy, as that he shall not be able to single out any one individual as his victim, but wear himself out in a crowd, the members of which are all equally attractive. This point, if duly worked out, might help to explain the curious subject of *fascination*, which some animals appear to possess over their prey.

THE PIGEON FALCON (*Falco columbarius*) is another American species, rather larger than the preceding one, and of a more bold and intrepid character. True to this character, it is a more northerly bird, breeding and rearing its young as far to the north as the inhospitable rocks which surround Hudson's Bay, and not appearing in the United States till the month of November, when the small birds congregate. "When," says Wilson, "the reed-bird, grackles, and red-winged blackbirds congregate in large flights, he is often observed hovering in their rear, or on their flanks, picking up the weak, the wounded, or stragglers, and frequently making a sudden and fatal sweep into the very midst of their multitudes. The flocks of robins and pigeons are honoured with the same attentions from this marauder, whose daily excursions are entirely regulated by the movements of the great body on whose unfortunate members it fattens. The individual from which the present description was taken, was shot in the meadows

below Philadelphia, in the month of August. He was carrying off a blackbird from the flock, and, though mortally wounded and dying, held his prey fast till his last expiring breath, having struck his claws into its very heart. This was found to be a male. Sometimes when shot at, and not hurt, he will fly in circles over the sportsman's head, shrieking out with great violence, as if highly irritated. He frequently flies low, skimming a little above the field. I have never seen his nest.

"The pigeon hawk is eleven inches long, and twenty-three broad; the whole upper parts are of a deep dark brown, except the tail, which is crossed with bars of white; the inner vanes of the quill feathers are marked with round spots of a reddish brown; the bill is short, strongly toothed, of a light blue colour, and tipped with black; the skin surrounding the eye greenish; the cere same; temples and line over the eye lighter brown; the lower parts brownish white, streaked laterally with dark brown; legs, yellow; claws, black. The female is an inch and a half longer, of a still deeper colour, though marked nearly in the same manner, with the exception of some white on the hind head. The femoral or thigh feathers in both are of a remarkable length, reaching nearly to the feet, and are also streaked longitudinally with dark brown. The irides of the eyes of this bird have been hitherto described as being of a brilliant yellow; but every specimen I have met with yet had the iris of a deep hazel. I must therefore follow nature in opposition to very numerous and respectable authorities.

"I cannot, in imitation of European naturalists, embellish the history of this species with anecdotes of its exploits in falconry. This science, if it may be so called, is among the few that have never yet travelled across the Atlantic; neither does it appear that the idea of training our hawks or eagles to the chase ever suggested itself to any of the Indian nations of North America. The Tartars, however, from whom, according to certain writers, many of these notions originated, have long excelled in the practice of this sport; which is, indeed, better suited to an open country than to one covered with forests."

The different characters of this and the preceding species of the American falcon, throws some light upon the differences of character in those birds, answering to differences in their geographical distribution. This is a more northerly species than the former, not being found at all in the tropical parts of America, and not in the temperate parts, except during the winter. Whereas the former is found most abundantly in tropical climates, and does not at all occur in the regions of the extreme north. This species is also a far more bold and determined bird than the other, and more decidedly a preyer upon the feathered tribes and the smaller mammalia. Something of the same kind occurs on the eastern continent. The small falcons which are most plentiful in the south and east of Europe, are very abundant in Asia; but the peregrine, notwithstanding its powers of flight, and its disposition to range, is by no means common there, and the jerfalcon is altogether unknown.

Hence we see that, in the polar countries, the falcon tribe take after the golden eagle as the grand type of all the tribes, while those in the tropical countries take more after the vulture. The former, in proportion as they are more northerly in their

proper habitat, prey more habitually upon warm-blooded animals, and kill their prey for themselves; the latter, in proportion as they are more equatorial in their peculiar habitat, feed more upon carrion and reptiles. In this there is a very beautiful adaptation. The equatorial pastures may be said to be perennial, and therefore their animals are mostly stationary or resident the whole year, and there is no particular period or season at which their numbers require to be thinned. Therefore, in as far as birds are concerned, scavengers only are wanted; but because the plains are alternately luxuriant with herbage, and burnt up with drought, we find the larger beasts of prey stationed there to keep down the superabundance of the grazing mammalia. In the polar countries, on the other hand, very many of the birds are migrant, and the winter is extremely severe, so that the numbers even of the resident birds, and also of the smaller ground mammalia, require to be periodically thinned. Did our limits permit, it would be easy to follow out this comparative view with reference to almost the whole of the animated inhabitants of the polar and tropical lands; but we must leave the farther prosecution of the subject to the reader, and proceed with our list of the remaining falcons, of which we shall not in general give English names, as they are not very applicable.

*Falco fusco-cærulescens.* This species, as its name imports, is brown and blue. The upper parts are bluish with brown markings; and the upper tail-coverts are streaked with white. The coverts and quills of the wings are brown; the under parts reddish with brown spots; the throat and breast brown with white streaks; the beak greenish-ash, and the feet ash-coloured. The length is about eleven inches, and the bird is an inhabitant of North America.

*Falco ophiophagus.* This name implies that the bird feeds upon snakes; but very little is known respecting its manners. It is described as being blackish-ash on the upper part, and greyish-white on the under; the top of the head, the throat, and sides of the neck reddish; the greater wing-coverts have white tips, but the rest of the coverts of the wings are black. The beak blackish-blue, and the naked parts of the feet blue. The upper mandible has a tooth towards the middle; and the lower a slight notch towards the point. The length is about thirteen inches, and the bird is found in North America, but its habits are not known.

*Falco albicollis.* The neck of this species, as the name imports, is white, which is also the colour of the head, and the under part of the body. The upper part is varied with white and blackish; the beak is ash-coloured, and the feet yellow. The bird is thus described; but there are two doubts respecting it,—first, whether it be a distinct species; and, secondly, whether, granting that it is so, it be a falcon.

*Falco nigricollis.* The general plumage is a mixture of black with reddish and white; the head, neck, and tips of the greater coverts are quite black; and the feet are yellow. Like the species immediately preceding, it was obtained from the northern parts of South America; but whether it be a distinct species is not known.

*Falco bidentatus.* This species is named from having the bill double-toothed. It is a native of tropical America. The upper part is of a grey colour, brightest on the head and cheeks; the under

part reddish, streaked with white. The throat and under tail-coverts white; the beak ash-coloured, and with two strong teeth on each side; the cere and naked part of the feet are yellow; and the length is about fourteen inches. The female is marked all over on the under part with small blue spots. The young are brown streaked with white on the upper part, and white streaked brown and reddish on the under.

*Falco superciliosus*. This is also a South American species, and has a naked space under the eyes. It is described as being brown on the upper part, and having the rump marked with black and white; the lesser coverts of the wings are ash-colour streaked with black; and the greater coverts have two white bands near their terminations; the under parts are whitish waved with brown; the eyebrows are projecting; the cheeks naked; the beak black; and the cere and feet yellow. This species, like many of those described from single museum specimens, is very doubtful.

*Falco femoralis*. This is also a South American species, and is described as a native of Brazil. The upper parts are bright brown; some of the wing coverts are marked with bars of reddish ash; the greater coverts are black, with white bars across at their bases, and red tips; the primary quills have white tips; there are large black mustachios; the forehead, cheeks, thighs, middle of the belly, and under tail coverts are bright red; the sides of the belly and the flanks are purplish black; the beak blue; the cere yellow; and the feet ash-coloured; the length is about twelve inches.

*Falco diodon* is another Brazilian species. The upper parts are slate black; the nape, the sides of the head, and the cheeks, deep ash colour; the throat white; the under parts greyish ash; the thighs reddish; the wings and tail barred with black; the beak ash-coloured, with two strong teeth to the upper mandible; the irides and feet yellow. The length is about eleven inches. The female has the markings less distinct. The immature birds are brown on the upper part, with streaks and bands of a darker colour; they are spotted with blackish on the under side; and have their thighs reddish.

*Falco meridionalis*. Brown on the upper part; head streaked with red and black; coverts streaked with whitish; under parts whitish with ash-coloured streaks; bill black; cere and feet yellow; length about sixteen inches.

There are several other species found in South America which are described as falcons, but nothing is known of their manners. There is as little known respecting the falcons of Africa, and indeed of all the warmer parts of the world, and the lines of distinction between them and the other birds of prey are very faintly marked, but we shall give a few of the names.

*Falco melanopterus*. Reddish on the upper part, with black and ash-coloured markings on the wings; under part white; beak blackish, and feet yellow. Length about fourteen inches.

*Falco Aldrovandii* is a small species, only between ten and eleven inches in length. It has been found in Java. The upper part, and the quills next the body, blackish blue; the wing coverts black spotted with red; the lower part reddish; the beak bluish; and the cere and feet yellow.

*Falco chicqueca*. Another small species very common in the interior parts of India. Upper part

bluish; nape and crown reddish; under parts white streaked with ash colour; the extremities of the tail feathers reddish with a black band; beak, irides, and feet yellow.

*Falco lophates*. Upper part, thighs, and belly of a black colour with blue reflections; some of the coverts of the wings marked with white spots surrounded by a reddish margin; a white band on the breast, the ground colour of which is maroon brown; a large crest on the hind head; the beak blue, with the edges of the mandibles yellow; the legs ash-coloured. The length about thirteen or fourteen inches. Inhabits India, and other parts of south-eastern Asia.

*Falco cirratus* is another Indian species with a crest. Upper part black; a long crest of a yellow colour on the nape, which parts in two and hangs over each side of the neck; the tail feathers banded with ash colour; the under part white lined with black; beak blue; irides, cere, and toes yellow; the tarsi feathered down to the toes.

*Falco ruficollis*. Understood to be an African species. The upper part brown; the head streaked with reddish brown and black; the tail feathers barred with white; the under part dull white marked with brownish ash and black; the throat white; the bill black; and the feet yellow. Length about fifteen inches.

Besides those of which we have given the names, there are many falcons of which specimens have been brought from remote parts of the world,—from South America, from Africa, from Asia, north and south, from Australia, from New Zealand, and from some of the remote isles of the Pacific. Indeed it should seem that no part of the world is without its falcon; though it is only in Europe and western Asia, that falcons have at any period been trained so as to be of the smallest service to the human race; and therefore those ones of which specimens are obtained from remote countries are birds of little or no interest, except to mere collectors; and in the case of some of them the collecting is as likely to be productive of error, as of truth. This is especially true of falcons and all other birds which are, or which at least some time ago were brought from Southern Africa; as any one can find by examining Levaillant's birds of Africa, many of which are not African birds at all; and when skins of animals are brought from dealers at the Cape, the purchaser would require to ascertain very correctly whether they are or are not natives of that quarter of the world; because from the Cape being a sort of *entrepôt* between Europe and the East, all oriental commodities and the skins of animals among the rest are of course to be had in abundance there. For these and other reasons we shall not extend the catalogue of the falcons properly so called; but we may remark in passing that the whole of those foreign ones appear to fall into three classes, of which the peregrine, the hobby, and the kestrel appear to be the European types, and, according as any foreign species resembles the one of these more than either of the other two, we may expect a correspondence in its habits to that which it more nearly resembles; and perhaps, in the present state of our knowledge, this is the best key which we have to the general characters of those birds. It must, however, be received with some modifications, because, as we have said, the characters of all the genus appear to be softened in proportion as their locality is nearer to the equator. We

shall now proceed shortly to notice the remaining, smaller and more local division of this genus of birds :—

**JERFALCONS** (*Hierofalco*), Cuvier. This (for though it is probable that there are three distinct species, yet we are well acquainted with only one,) is the most powerful, and in some respects the most interesting of all the falcons. In the structure of its wings it resembles them exactly; being adapted for rising against the wind, and not floating by the wind's motion. The beak, however, differs from that of the other falcons, in being almost without a tooth, having merely a bend downwards near the tip of the upper mandible, and a very slight notch in the under. It is in fact, at least in so far as its cutting edges are concerned, more like the beak of an eagle than that of a falcon; but it still retains the curvature from the base, and in its general structure it is a very powerful instrument, more powerful perhaps than the beak of any other genus, not so much on account of its greater size as of its superior strength, and the firmness of its texture.

Jerfalcon.

This form of beak in the jerfalcon shows how unsafe it is to form our general notions of birds upon the structure of any general organ. It has sometimes been supposed that, in consequence of this want of a tooth in the beak, the jerfalcon was allied to the vulture; and some have gone so far as to say that the first part of its compound name "jer" is nothing else than *gyer*, the name of a vulture in the north Alps, altered in the pronunciation. Whether this be or be not the case, is of little consequence; but the probability is that it is not true; because there is no vulture in the native locality of the jerfalcon, and we believe there never was an instance of a jerfalcon in a state of nature appearing in a vulture's country, even as a straggler. There could therefore be no means by which the rude people of former times could so compare these two birds, as to decide upon their similarity or their dissimilarity; and therefore we must regard such observations as this in no other light than that of fancies, which systematic naturalists are sometimes apt to indulge in when they know not very well what else to say. The truth is, that there is perhaps no bird of the whole rapacious order that differs more from the vulture in its manners, and also in its geo-

graphical distribution, than the jerfalcon does. As a diurnal preyer, the jerfalcon tenants the arctic margin of the land, and has to maintain its existence and find its food amid the storms and the comparative desolation of the north. And we may add, that there is no creature within the whole compass of the animal kingdom more admirably adapted to the scenes which it tenants, and the atmosphere through which it has to make its way. Its bones are more compact and strong than those of any other known bird, being of greater specific gravity, volume for volume, than those of the golden eagle herself, though she too is a dweller in stormy places, and has to beat the wilderness far and wide for her subsistence. If we take those bones singly, each of them is a perfect model of the maximum of strength and the minimum of their materials; and if we look at them in their connections, their articulations, and those levers and purchases which they afford to the tendons of the muscles, there is more of the principles of mechanics to be learned from the skeleton of a jerfalcon than from all the combinations of materials which were ever brought together by human engineers. Then, if we proceed to examine this matchless skeleton as it is clothed with flesh, enwrapped in skin, and protected and furnished with feathers we find in this bird one of the most striking, one of the most irresistible proofs of infinite wisdom in contrivance, and infinite power in execution. Viewed in this light, the jerfalcon, clutching the summit of the ice-clad rock, or breasting the northern tempest when it drives dark as midnight with snow, proclaims as loudly the existence and the attributes of her Maker, as if they were written in a book, in the most forcible terms, and in all the languages under heaven.

We shall afterwards say a few words on the probability of a difference of species, or at all events a variety in this most noble bird; but we are in the mean time treating of it as the one well-known jerfalcon, *Falco islandicus*, of most authors; and while treating thus generally we shall quote the following passage from Mudie's Feathered Tribes of the British Islands: "It has not been positively ascertained that the jerfalcon breeds in any part of the British islands, neither can the fact of its so breeding be denied, because, in all places, its nest is situated so high among the crags of the rocks, that it is difficult to be seen, and still more difficult to be reached. But, if it does not breed there, it pays occasional visits to the northern and western isles, more especially to those places of them that abound with rock doves; and few sights can be finer than that of the jerfalcon driving through a flock of these. When the falcon comes within sight of her prey, she bounds upwards, every stroke of her wings producing a perpendicular leap, as if she were climbing those giant stairs into which nature moulds the basaltic rocks; and when she has 'got the sky' of her prey to a sufficient height for gaining the necessary impetus, her wings shiver for a moment as she works herself into perfect command and power, and to the full extent of her energy. Then down she dashes, with so much velocity, that the impression of her path remains on the eye, in the same manner as that of the shooting meteor or flashing lightning, and you fancy that there is a torrent of falcons rushing for fathoms through the air. The stroke is as unerring as the motion is fleet. If it take effect in the body, the bird is bruised and her hunt is over; but if a wing only is broken, the maimed bird is allowed to flutter to the earth, and another is marked

out for the collision of death. It sometimes happens that the mountain crow comes in for the wounded game; but in order to do so it must proceed stealthily along the ground, for woe betide it if it rises on the wing, and meets the glance of the falcon. The raven himself never scoops out another eye, if he rises to tempt that one; and it is by no means improbable that, in the early season, in those cold northern countries, when the lambs are young and the flocks weak, and the crows and ravens prowling about blinding and torturing, the jerfalcon may be of considerable service to the shepherd."

The jerfalcon is large, strong, exceedingly compact, and very firm in its plumage. The length of the male bird is about twenty-two inches, and the stretch of its wings about four feet. The female is two or three inches longer, and proportionally greater in the extent of the wings. The ground colour of the whole plumage is white, with narrow bands of brown on the upper parts and the tail, and tear-shaped spots of the same colour upon the under part of the body, interspersed with lines and arrow-point spots still of the same colour. The tail, which consists of twelve rounded feathers, is rather long, of a dark-greyish colour, with black shafts to the feathers, and marked across with dusky bars, generally about twelve in number. The colours on the upper part of the male bird are, at all ages, darker than those of the female; and the very old females become almost white. It is probable also that, as is the case with the ptarmigan, which forms part of the jerfalcon's winter food, the white may become more pure during the winter season. The beak is of a bluish colour, but the tip is black, and so are the claws. The feet, the cere, and the naked space round the eyes are bluish yellow. In the young bird they incline more to blue, and the upper part is also much more dusky, so that, as has been the case with many other falcons, the old and the young have been sometimes described as different species. The tarsi, which are very short, and have reticulated scales, are feathered for the upper part of their length. The feet and claws are not remarkably large; but the action of the joints is exceedingly powerful and the articulation beautiful.

The extreme north of Europe, and also of some parts of Asia, is the native locality of the jerfalcon. On the continent it is not met with to the southward of the Baltic, and it is rare in the southern parts of Sweden. Indeed, as it is completely a bird of the wilds, it seldom makes its appearance over cultivated lands in any country. It is not, however, a woodland bird, but a tenant of the wild rocks; and though it is plentiful in Norway, Iceland, in which there are no woods, is understood to be its head quarters, and the country where it attains the largest size, and has the greatest power,—if indeed there be not in Iceland a species, or variety, of greater size and strength, and whiter in the colour than the one which is met with in continental Europe.

The jerfalcon certainly does combine some of the habits of the golden eagle with those of the falcons properly so called; and the structure agrees with this habit. Ascent and descent, the former to gain power, and the latter to put that power in execution, are the chief motions of the eagle; and for this purpose the eagle has great strength and capacity of action in the tail; so that it works for ascent or descent, something in the same manner as the wings work for progressive motion. The tail of the jer-

falcon is in this respect very similar to that of the eagle; it is capable of being spread very wide, and of striking either upwards or downwards against the air, with very considerable force. At the same time, the very different structure of the wings gives this falcon a far greater command of the air than the eagle. The eagle can do execution only when her prey is on the ground; and she cannot rise to windward in the same style as the falcons. The jerfalcon on the other hand can strike her prey either in the air or upon the ground, and with the same effect in both cases. It is probable that the use of these different powers predominates at different seasons. In summer the places which the jerfalcon inhabits are full of birds, snipes, lapwings, and other birds of rapid flight, besides the native gallinaceous birds of the northern wilds. Some places too, even pretty far north, have their rocky shores thronged with rock doves (*Columba livia*); and during the summer season these are generally stirring. At this season, therefore, it is probable that the jerfalcon lives chiefly upon birds, and kills her prey in the air; but that when winter comes she has to take more to the habit of the eagle. At that season there are comparatively few birds to be seen on the wing; though there are a good many ground birds, as well as alpine hares, and other small mammalia; and, though we cannot be certain of the fact, it is highly probable that during this season the jerfalcon preys upon these.

In farther proof of this, it may be mentioned, that it is in summer and autumn, rather than after the winter has set in, that the jerfalcon is discursive, and found without her arctic territory; and this fact shows that she must be supported during the winter by food which she finds at home; and that which we have mentioned is the principal part of what her dominions then furnish. In this again there is some resemblance to the golden eagle. The upland places which the golden eagle frequents, stand to the low countries around them in pretty nearly the same relation as the native haunts of the jerfalcon stands to the temperate countries farther to the south. And it is matter of common observation to those who reside near the abodes of eagles, that they seldom or never find those birds beating over the lower valleys in the winter. Indeed, they are rarely seen at that season; but as we know that eagles stand many winters, they must have some food, notwithstanding their power of abstinence; and this food they must obtain in the mountains. The jerfalcon is, in all probability, as long lived a bird as the eagle; and though she is probably as capable of enduring hunger as the eagle, we can scarcely suppose that she can be without food for the whole length of a Lapland or an Iceland winter, which is any thing but a short one, and consequently she also must find what food she acquires in the wilds during this season.

Those circumstances, which we believe have seldom if ever been adverted to, are worthy of attention, as descriptive of the leading habits of perhaps the two most interesting birds in the whole of the feathered catalogue. They are both tempered to the utmost violence of the storm; and they remain most constantly in the home of that storm during the season of its greatest violence. This is very different from the birds of warmer countries; and from the summer visitants of the colder ones; but it is common to the gallinidæ of the northern regions and the mountain tops, as well as to the powerful birds of prey which winter there. The great owls of the north should

probably also be included in this peculiar class of birds; but this is not the place to notice them; and, therefore, we shall reserve what we have to say concerning them till we come to the article Owl, in which we shall take occasion to examine the peculiarities of the whole family of the *Stringida*, as they are sometimes called in modern nomenclature.

In their excursions, even at that season when they spread the most, the jerfalcon is rarely if ever seen in England, and we believe they are equally rare in the lowland and well-cultivated parts of Scotland. They appear, however, not unfrequently in the Shetland islands, rather less so in the Orkneys, and less so still in the western islands, and the west and north-west islands of Scotland. When they do make their appearance there, however, they are easily known from any other birds of prey by their colour, their size, and the splendid style of their flight. We have been informed by those who have been much in the open air, and were attentive to what was going on in these places, that jerfalcon is nearly white, and others much darker, are occasionally seen, though of course not together; and that the paler-coloured ones are larger, bolder, and of more powerful wing. This would lead one to conclude that the pale ones are from Iceland, and those of a darker colour from Norway, by the way of the northern isles; and, as the rate of flight in a jerfalcon is in all probability not less than one hundred and fifty miles in the hour, none of the distances which we have mentioned would be very fatiguing. We are still, however, in want of more information respecting the habits of these birds; and also respecting another species, darker coloured than either of these, which is said to occur in the northern parts of the American continent.

We omitted to mention that jerfalcon nestle on the ledges or in the clefts of the rocks; that the pair are generally near each other during the time that they have young; and that the number of eggs varies from two to four. Jerfalcon is the most esteemed of the whole race, though the most difficult to train; and, therefore, they were, and in some places are still, in great request. Even as far from their native north as Persia the female was used in bringing down the most powerful birds, such as the stork and the crane, while the male was employed against the heron, the kite and the crow. But we must end this part of our subject, as we have not space fully to enter into its details.

**FALCONRY.** The natural history of the falcons would be incomplete without some slight notice of the use of them in the art of falconry, and the training of them for that art, even though, as a regular sport, it may be said to be now wholly extinct in this country, and very much on the decline in every other. The fact is, that of all engines, so to call them, used for the capture or the killing of game, falcons are by far the most expensive, and require the most skilful management, both in training at the first, and in exercising them so as to keep them in training.

The art is not a modern one; for it was known in the time of the Romans; and it is not impossible that, as was the case with most sciences and scientific sports, it had its first beginning in Egypt. It would be foreign to our purpose to enter into the details of its history, farther than to mention that, though perhaps it may be reckoned a savage sport in itself, it is one the practice of which pre-supposes a very considerable degree of observation of the habits of animals, and of inference founded upon this observation—more

indeed than could be expected from any rude or barbarous nation; and, accordingly, we do not find that any uncivilised people ever employed falcons in the chase of birds, how much soever they may have abounded in their locality. Neither does it appear from any of the older writers that any attempt was made to reduce the flight of falcons to any thing like principle, until about fifty years ago.

Notwithstanding this, the division of birds of prey into noble and ignoble, and of such of them as were used in falconry into noble and ignoble hawks, is as completely founded upon structural difference, as if Cuvier himself had dissected and investigated them, muscle by muscle, and bone by bone, in order to determine in which way their active powers could be most successfully employed, and in what respects the one division differs from the others.

In classing those birds according to the relative powers of their wings and their modes of using them, the French writers, who have treated this subject with attention, distinguish them as *rowers* and *sailers*. The distinction between those two terms is exactly that between the noble and the ignoble hawks; only the kestrel, which was not used in falconry, rather disturbs the arrangement, by so far agreeing in wing with the kites, though its principal characters are those of the falcon.

In the rowing birds, the bones of the wing are remarkably perfect; and the bodies of the birds themselves are formed in such a manner as to offer the least forcible resistance to the wind, when the head of the bird is directed against it. The feathers are remarkable for the strength and elasticity of their shafts, and the closeness of their webs; so that while the feathers of the wings can strike against the air with great force, they are not laid hold of by it, and carried along by its current, as is the case with birds of more flocculent feather, and differently formed wing. The ten quills which are nearest the extremity of the wing, and which thus have the most rapid motion and produce the most powerful effect when the wing acts, are continuous, and have their barbs more firmly interlinked with each other than in any other birds. When the wing is raised, indeed, openings are made which admit its upward motion with comparatively little resistance, and the firm terminations of the barbs have an advantage in this respect; but when the wing descends, which of course is the stroke in flying, this most powerful part of it strikes as if it were the blade of an oar of the best construction. Those wings are narrow in proportion to their length, as compared with those of birds of inferior flight; they are also nearly flat on their under sides, and the under coverts and feathers are smooth and firm up almost to the junction with the body. In ascending flight, the birds do not carry the axis of the body horizontal, but have it at an angle, with the head considerably elevated, and the line of the body forming an angle with the wind, which of course the bird regulates according to the wind's velocity. A good paper kite seen in the air during a breeze, when the boy who manages it is running to windward, gives no bad idea of the position and even the motion and action of the rowing bird, or noble bird of prey, when it is rising against the wind; and in order to make the illustration almost perfect, we have only to consider that the gravitation and muscular action of the bird performs the same office as the string of the kite, and the muscular action of the boy in running along the ground. Such is the

structure of the wings in the rowing birds; and we shall shortly mention this in the sailing ones, before we come to speak of the peculiar mode of action in each, and their different adaptations in the art of falconry.

In sailing birds generally, and in the ignoble birds of prey, the whole structure and texture of the wings are different. The bones are shorter, less firm in the joints, and less completely stretched in the act of flying. The quills of the extreme part of the wing are gradually shortened for about four from the longest feather, which is never the first or second, and is the fourth in the gos-hawk, which may be considered as the typical hawk, and was the one of the sailers that was the most esteemed in falconry. A wing of this structure acts much less powerfully upon the wind than one of the former. The tense bones of the former wing enable it to strike the air with its whole force; but this one, in consequence of its being looser in the joints, and less extended, "gives" to the stroke, so that the one strikes like a firm, though somewhat elastic rod—the other like an apparatus to a certain extent jointed. The surfaces and terminations of the webs of the feathers also give themselves more up to the air than in the rowing birds. They are more loose and flocculent, not only in their clothing feathers and coverts, but in the quills beyond the coverts. This is apparent in their very appearance. The quills of the noble hawks are smooth and glossy to their very extremities, while those of the others have a dead colour, as if they were covered with some sort of fine powder, or very short nap, and the latter is the case. The covered part of the wing is also broader in proportion, and more loosely feathered; and it is hollow not only in the direction of its length, in consequence of the imperfect stretch, but it is hollow also in the cross section. In short, it is a wing of which the wind can take hold, just as it does of the belly of a sail. Such a wing is of course ill adapted either for rising or for progressive motion against the wind, but it is equally well adapted for going with the wind, and also for all sorts of short action in the air, in places where the wing of a falcon would not have scope for its more powerful action. Such a wing, and the general plumage of the bird answers to it, upon the principle of harmony which runs through all nature's productions, is calculated for leaning on the air, or hovering, as it is usually called, for a far greater length of time, and in finer style, than could be done by the rowing bird, no part of which is adapted for taking a hold on the air. Wings of this description are also, generally speaking, shorter than those of the other, and this adds further to the accommodation of the sailing bird in those situations for which it is best fitted. Such are the general characters and distinctions of the wings in the two sorts of birds used in falconry.

There is also a very considerable difference in the structure of the feet. In the rowers, or noble hawks, the tarsi are always short, and, generally speaking, they are short in proportion to the power of the bird. The toes, also, have great power of motion, and the claws are very sharp. In the short-winged birds the tarsi are always longer, often pretty long in proportion to the size of the bird; and though the toes are perhaps not, upon the whole, less powerful, they are not fitted for such rapid and immediate action as those of the other division. There are some other peculiarities, such as more looseness in the general

form of the body in the short-winged bird, but those of the wings and feet, as above mentioned, are the most important; and as the whole structure of the bird is in accordance, those minor particulars may easily be inferred from what has been said.

Now, if we consider either the localities of the two divisions, or the manner in which they obtain their prey, we shall perceive how beautifully each is adapted to its purpose, and how much both would be at a loss if they were made to change places. The falcons are birds of the open grounds, of the rocky mountain, and the wide moor, and their prey, in so far as it consists of birds, is killed by the stroke delivered in the open air, and not clutched with the talons; for, when a falcon hunts in good style, she strikes her prey to the ground, and descends after it. The hawks, on the other hand, are more birds of wooded places, where they have many turnings to make, and do not require the straight-lined rush of the falcons. In catching their prey, they clutch it with the talons rather than strike at it, and the length of the tarsus seems to assist them in this process. The eagle, which is a broad-winged bird, and the kite, which is a bird with wings of rather a mixed character, form exceptions to this, as the eagle is invariably, and the kite generally, found in open places, though the latter frequents the neighbourhood of woods. Both of these, however, prey upon the ground, and are clutching birds rather than striking ones; but as neither of them was trained for falconry, they do not require a further description in the present place.

There is something worthy of remark in the different manner in which the falcons and the hawks attack their prey. The falcon, of whatever species it may be, always aims its blow at the most vulnerable part of its prey, or that which shall most instantly occasion death; and in birds this vulnerable spot is the nape, immediately at the articulation of the skull with the vertebral column, so that a stroke given here, of the force with which even the lightest of the falcons rushes upon its prey, is sufficient to fracture the skull, or dislocate the neck. So accurately is this done, that the merlin, light as it is, will strike dead to the earth a bird heavier than itself, with so much rapidity as that it can hardly be perceived; for it is no sooner in contact with the living bird than the dead one separates from it. Hawks, and sailing birds of prey generally, are not so particular as to the place at which they aim their stroke; their object is rather to clutch their prey, and hold it by main strength, until they have strangled, or otherwise pressed and torn it to death. We cannot help noticing here a remarkable coincidence between different divisions of predatory birds and predatory mammalia. All the clutching and crushing mammalia, which catch their prey by lying in wait, or by other stratagems, seize it indiscriminately by any part, and either run it down, under the double effect of their weight and the torture which they give by their teeth and claws, or they crush and rend it. But the coursing mammalia, which run down their prey in open chase, invariably seize upon some vital part, as is observed in those dogs which are in the wild state, and in ill-bred domestic dogs, which so far return to their wild habits and savage propensities, as to prowling about at night and bite sheep. A practised canine thief of this description will sometimes, in the course of a single night, kill and bleed more than a dozen sheep without in the least tearing or breaking the carcasses;

whereas, if any animal is seized and killed by one of the feline or clutching race, no matter for the species, it will invariably be found to be mangled. Those coincidences between animals of different classes, in respect of their modes of action, are among the most interesting points in natural history, because they give us two lessons of the utmost value—the one for our instruction in a scientific, and the other in a moral point of view. In the first place, they clearly demonstrate, that if we once properly get hold of a principle, and follow it out into its details, so as to see everything respecting organisation, locality, and habits, we can proceed by analogy from these, and greatly abridge the labour of acquiring a knowledge of other parts of the system. In the second place, they demonstrate, that the law of nature is one, that purpose and adaptation run uniformly through the whole creation, and that therefore the Author and Governor is one.

It is not very easy to give, in few words, such a generalisation of the action of these birds as can be considered popular, and yet it is so much connected with the action of animals generally, and with that of feathered animals in particular, that every body should understand something about it. It may, in general, be said that the falcons, and birds which are winged and feathered like the falcons, are capable of making the greatest possible use of the air, while the air has the least possible effect upon them; and that the hawks, and birds winged and feathered like the hawks, are always in so far at the disposal of the wind, though less so than the majority of those birds on which they feed, otherwise there would be no food for the hawks, unless what they could get by stratagem and lying in wait, as is done by the greater majority of the owls.

As the air has comparatively little hold upon either the wings or the feathers of the falcons, they can keep their intended course with much less labour and more certainty than those birds whose wings and feathers take hold of the wind. This, however, prevents them from being able to wheel and double so quickly or within so small a compass as the others, and therefore they can be effective only in situations where they have scope for their wings. In the free expanse of the air, however, they have advantages which no other birds possess, and thus the wing of the falcon may, in its proper element, be said to triumph over every other wing. No bird that rises down the wind can gain much additional height without being carried to a very considerable distance in the direction in which the wind blows; and no bird upon whose feathers, whether those of the wings or the body, the wind takes a powerful hold, can fly across the wind without making a good deal of leeway, and being thrown out of any aim which it may have taken, while the hold which the peculiar texture of its feathers takes on the matter of the atmosphere must tend very much to retard its motion even when the air is still. But all these circumstances, disadvantageous as they are in forward flight in the free air, are of use to the short-winged birds in the way in which they in general act. Such of them as look out for ground prey can, by this means, float and hover till they have scoured the whole of an extensive horizon; while those which prey in the woods and among bushes, can turn and glide, so as to come upon their prey with greater ease. They are also muffled, as it were, by the

formation of the margins and surfaces of their feathers, and thus they can range in comparative silence those places where the sound of the firm wings of the falcon would give instant warning of her approach. Thus, in the free air over the wild, nothing which she marks out as her prey can escape the bold pursuit of the falcon, though there are many birds that in such places can defy the hawk. On the other hand, when the range is interrupted, or the bird flies low and doubles, the hawk can keep sight of it and wear it out, when all the strength, force, and rush of the falcon would be quite unavailing.

In illustration of this, we may mention an instance of the superiority of falconry over hawking in the open plains, which was observed in a remote district of the Scotch Highlands a few years ago by a friend of the writer of this article. It was early in the season, and long before shooting on the moors commences, that our friend, in company with a resident veteran of the hill, who knew the habits of every creature that appeared on it, had wandered nearly as far as the water-shed in one of those wide and half-boggy passes, which are so much resorted to by the semi-aquatic birds which breed in the inland wilds. When they had fatigued themselves with the heavy footing through heather, and moss, and long grass, they sat down upon a "a rest-and-be-thankful" stone, to survey the glen, of which the height that they had now gained gave them the command, they observed a large light-coloured bird of prey in pursuit of a lapwing, which was doubling about in all the ways that its very hollow wing admits of; and as the wind was from the hill, their progress was, upon the whole, down the glen before it. The falcon, from its apparent size and the whiteness of its colour, was either a full-grown jer, or one of the larger variety of Iceland (if that is a variety); but still, what with the doubling, what with the advantage of the wind on the concave wings of the prey, the falcon lost rather than gained, and had it persevered in this kind of chase, the lapwing would have worn it out. After some time spent in this hopeless pursuit, the falcon turned round to windward, in the very opposite direction to that in which chase had been given. Our informant expressed his surprise that a bird of such apparent power should thus abandon her prey. "She will return," said his companion, "or else she is not true either to her colour or her course; that is not the way in which falcons abandon their game." They watched the course of the falcon, which had risen at a comparatively small angle with the perpendicular, till she seemed no bigger than a lark; and the lapwing, alarmed by the pursuit, was still wheeling about in the air at no very great distance. At last the falcon halted and turned, and her wings began to shiver in the air. "Mark now," said the mountaineer, "whether she has or has not abandoned her game." In an instant, she shot downwards with the rush of an arrow; the lapwing gave one shrilly wail, and appeared to lose all command of its wings; and in less than a minute they heard the sound of the stroke, and the lapwing fell to the earth, from which it again rebounded by the violence of the fall. They of course left the falcon to enjoy in peace that feast in the obtaining of which she had shown so much science.

No birds are thrown into greater consternation by the flying of a falcon over them than magpies; and although this kind of sport makes nothing for the "pot," it shows in what dread the falcon is held,

The best way is to watch for a time when the magpies hold one of those councils which are not unfrequent among these curious birds, and then to let fly the falcon. The council is generally held at no great distance from some cover, such as a broom or furze-bush, and the magpies have generally all their eyes about them, so that they espy the falcon as soon as she is in the air. Then it is "hurry-skurry" for the cover, into which they creep, and lie so close that the whole posse may be taken with the hand. If there is no cover which they can reach, they squat flat and motionless on the ground, and may be picked up in the same manner. We know not how the jer might come on in the event of being flown at the raven; but we once saw an instance of the common falcon, in which it appeared to be a drawn battle between the two, and as the companion raven was approaching, the falcon, but for human aid, would have been the victim.

To observe the action of these birds, whether the flight be low or high, is a very easy matter; and after the principles of mechanics, and the structure of the birds are once fully understood, it is by no means difficult to explain the *rationale* of their action, and to show how admirably each is adapted to the place which it holds, and the functions which it performs in animated nature. But after this is done the grand difficulty remains behind, namely, how the powers of these, apparently the wildest and most wayward of all living creatures, should be brought into complete subjection to man, and made as obedient to his command, as if they were endowed with reason. This, however, has been done, and done so completely, and under such different circumstances of species and of age in the birds, as to leave no doubt that, by due attention and proper training, man might press every power and every faculty of the animal kingdom into his service,—that, for instance, he might make the porpoise, the seal, and the pike catch fish for him as readily as the hound catches hares, or the falcon strikes down pigeons. Nor is it at all unlikely that, amid the vast improvement which has of late years taken place in the mechanical use of dead matter or the application of its chemical powers, the capabilities of life have been too much neglected; for we may rest assured that the use to man of every thing in creation, if he could once find it out and know how to apply it, is in exact proportion to its energy in the wild state; and this is the chief reason why the training (for it cannot be called taming) of these birds of prey is so worthy of attention.

For the purpose of falconry, hawks were not in general bred in a state of captivity, and indeed the falconers who had charge of them used many arts to prevent them from breeding. There were three ways of obtaining them, or rather they were obtained at three different ages. The young birds when they could be found in that state were taken from the nest, while they were yet covered with down instead of feathers. In this state they were, in the language of falconry, called *simples*, and though they were longer in being ready for use than the more advanced ones, their education, from being begun so early, was much more easy. Another age at which they were perhaps more easily procured, was that at which they were so far fledged as to be able to quit the nest, but not so much so as to be capable of flight. In this state they were termed *branchers*, which term was in all probability derived from those species which

build their nests in trees. These were a little sooner ready for action than the *simples*; but their education was considerably more difficult, as they had acquired more of their natural character in the wild state before their education began. The third means of obtaining them was, catching the wild birds in nets by means of various stratagems, which had to be varied according to the species. The birds obtained in this way were of course much sooner fit for sport than the younger ones; but the training of them was a matter of much more difficulty. Those birds which had acquired their natural character in whole or in part, before they came into the hands of the trainers, were called *haggards*, and the same name was bestowed upon refractory hawks and falcons, which were sometimes in the habit of breaking away from the game for which they were trained, or of flying off with the game and not returning to the falconer. Birds which had this habit were held in very low estimation; as may be judged of by a very beautiful, though metaphorical allusion in Shakspeare's tragedy of Othello. Iago had just worked up the Moor to the requisite pitch of jealousy, and left him to the agony of his feelings; and in his frantic soliloquy he is made to give utterance to the following words among others—

If I do prove her *haggard*,  
Though that her jesses were my dear heart-strings;  
I'd whistle her off, and let her down the wind,  
To prey at fortune.

This passage, short as it is, contains a pretty ample epitome of the characters of falcons, though the poet has a double meaning in the word "*haggard*" in allusion to human frailty. If she acted as a rebellious falcon, untrue to her training and trust, then she was to be sent, after the manner of the ignoble hawks, to provide for herself as she best could.

It would be too long to point out all the steps in the education of hawks; but at whatever age they were taken, the first thing to be done was to attach small bells to their feet, so as to accustom them to noise every time they moved. If *simples*, they were provided with *eyries*, which were shutters lined with straw, placed at a little elevation for the birds of high flight, but on the ground for the low-flighted ones; or, if the nest be naturally in such situations, the rock breeders were placed on the top of a wall or heap of stones, and those which breed in trees had a nest for them placed in a tree at no great height. Near the openings there were boards placed, on which they were made to perform their first exercises, and on which also they were fed, in order to attach them to the place in which they were exercised. Their food consisted of beef or mutton, but especially the latter, which is indeed the best food for them at all ages; and must be freed of all the cartilage and fat, and cut into slender and not too long shreds, but the more recent it is and the more blood that there is in it, they eat it with a greater relish. As soon as the low-flighted hawks were able to descend from the board and get up again, their food was placed on the ground.

When the unfledged young are taken from the nest, this nursery treatment is continued for about six weeks, and if they have been properly fed and attended to, they are by this time able to catch such small birds as come within their reach, which shows at how early an age birds of this description begin to catch prey for themselves. Up to this period the birds are allowed the full enjoyment of their liberty, both because they are too young for entering upon

their formal training, and because they need to acquire some strength; but when they are able to catch small birds, the *jesses* or wops of leather are put round the tarsi, and a ring and cord attached, by which they are confined during great part of the training, and the jesses remain, in order that they may be confined by these whenever it is necessary, as confinement by the feet is the surest way to keep them from injuring themselves or anything else. The branchers are much sooner ready for putting in training than the unfledged young, but the training is proportionally difficult, because the others have been accustomed to noise, and the sight of men and dogs, during their nursery treatment.

Falconers used to prefer nestlings when they could be obtained, because their training was much more sure as well as easy, and next to these they preferred branchers. When none of these could be obtained, then the object was to capture full-grown birds. The smaller ones were obtained in common bird-nets, by descending on the call birds; and the goshawk, and even the falcon were sometimes caught, but much more rarely, though the latter was frequently enticed by a pigeon and a tame falcon. Owls were also made use of for the purpose of enticing the falcons and the larger hawks into the net. The jerfalcon, from its superior power and wildness, was much more difficult to be taken in snares than any of the others; but then the jerfalcon was so much more effective against the larger game, and brought so much higher a price, that even she was taken in her fastnesses of the north, so that at one time there was a regular export of jerfalcons both from Iceland and from Norway.

In the case, both of the highfliers and the low, the difficulty of the training was pretty nearly in proportion to the value of the bird after it was trained, though the goshawk rather formed an exception to this, being much more docile and easily managed than even the sparrow hawk. Among the true falcons, the merlin was the most manageable, required less training than any of the rest, and came more readily at the call, neither did it so soon go out of training when not properly exercised. On this account, and also from the elegance of its form, and the certainty of its stroke, the merlin was a great favourite. The hobby, on the other hand, was a stubborn little fellow, and required nearly as much trouble to *reclaim him*, that is to make him return at the call of the falconer, as any of the larger ones, excepting, perhaps, the jerfalcon.

When mature birds of the stubborn species had to be trained, the first object was to reduce them low enough; and some nicety was required in order to subdue the bird sufficiently, without at the same time injuring its health. Low diet was one of the means resorted to, the food being reduced to half the allowance of a trained falcon, and its stimulating quality diminished by steeping it in water. Aperient medicines were also administered for the purpose of reducing the tone of the internal part of the system, and cold water was applied in order to bring down the tone of the muscular system. With the jerfalcon this training had generally to be continued for about six weeks before the bird was sufficiently subdued, he being kept blind-folded all this time by a hood. In order to ascertain whether the bird was subdued or not, they touched his head in various places, rubbing him at the same time with a pigeon's wing in a recent

state, and fresh with the smell of that bird and its blood. If the bird bore this teasing and temptation without excitement, and moved his head obedient to the hand, he was considered fit for occasional exposure to the light; but several weeks more were necessary in order to make sure of the bird's obedience. When this was achieved, they then taught the falcon to know and fly at the kind of game for which it was trained, by dressing up lures or imitations of the game, and placing food in the blood upon them. This was accompanied by teaching the bird to come back to the arm or hand of the falconer, which was accomplished by jerking away the food from the wire, and then giving a little food on the return to the hand. It is inconceivable how much care and trouble were required in order to reclaim a mature female jerfalcon in this way, for it was almost as much as, in the modern system of military tactics, would discipline a whole regiment for the field. Even after all this trouble had been taken, the jerfalcon required the most watchful attention, because it always retained a certain degree of irritability, and therefore could be turned to proper account only by a falconer who thoroughly understood his disposition. For these reasons, even at the time when the feudal system was at its height, and the many were, throughout Europe, the slaves of the few, and made to minister to their caprices, it was not every owner of a baronial castle who could afford to fly jerfalcons, and a good one was a becoming present for an emperor. Matters are somewhat changed in this respect now-a-days, and giraffes and elephants are almost the only animals deemed worthy of royal presentation.

The peregrine falcon was reclaimed with much less labour than this, and in much shorter time; and as the peregrine could be obtained in many countries where the jer could not, and farther, as she was much more docile and obedient to the falconer, and by no means liable to lose her temper, she was the falcon in most general use for high flight; nor are we sure that, for all her great power and her high price, the jer was ever complimented with the name of a "*gentle falcon*;" at all events, if she had the name she had none of the reality. In point of training, the hobby stood nearly in the same relation to the merlin that the jerfalcon did to the peregrine, and as its powers are not greater than those of the merlin, it was not held in so much esteem.

The training of low-flighted hawks was a simple matter compared with that of falcons, and scarcely required more days in the hands of a skilful reclainer than the jerfalcon required weeks. The goshawk was the favourite, both on account of its docility and its woodland habits, though probably the sparrowhawk is a bird of more spirit.

In all cases of training, the object was to have the bird in such spirit as that it would fly at its proper game or quarry the instant that it was unhooded, and return again to the arm of the falconer whether it struck or missed its prey. In addition to this, there were many qualities of a good hawk dependent on the animal itself as distinguished from others of its species, but it does not appear that the labours of the reclainer had much to do in the production of these. The great use which was made of cold water in training those birds, and also in reducing them when excited, or keeping them low and even in health at those times of the year when they were not used in

sport, is worth attending to, the more so that the same application very speedily takes down the heat of the temper of other animals. When dogs fight, there are no means of putting an end to their hostilities so speedily and so certainly as by sousing them each with cold water; and it is very probable that, in many other cases of animal irritation or stubbornness, the same application would be equally effective. Indeed, if in all cases in which animals naturally ferocious have been brought into subjection and obedience, the different steps by which this result has been arrived at had been carefully noted and duly arranged, we should have been in possession of a body of highly valuable practical information upon a subject of which we are in a great measure ignorant. Nor is there any doubt that if this could be fully and judiciously made a matter of science, very many of those creatures which we now pass by as useless, and persecute as noxious, might long ere now have been useful and obedient servants, and that whether they belong to one or to another of those classes which have sufficient size and strength for taking a part in labour. It is principally with a view to recommend this, that we have written the present article, because the subject is one upon which we must have a great deal of practice before we can have any theory.

**FASCIOLARIA** (Brugnières; *MUREX*, Linnæus). This genus of molluscs was classed by Linnæus with the *Murices*, and the French naturalist Brugnières appears to have been the first to point out the propriety of a separation; but he was not sufficiently accurate in his observations, and confounded them with the genus *Fusus*, also another of his own separations from the *Murices*. The *Fasciolaria* may at once be distinguished from the *Murices*, by never having any varices, though it has a canal at the base; from the *Fusus*, they differ by having plaits on the columella. This circumstance brings them nearer to the *G. turbinella*, but in that the position of the plaits is *transverse*, while the shells of the present genus are *spirally* oblique. The form of these shells is fusiform, the spire of a moderate length, the aperture oval, lengthened, nearly symmetrical, terminated by a rather long straight tube, the external margin sharp, and the columella furnished with two or three oblique plaits; the whorls of some species are nodulous, it has an epidermis, and possesses a horny operculum. The name of the genus is derived from *fasciola*, which word describes its characteristic distinction. Modern naturalists form a natural association of the species, as follows:—those whose shape is fusiform, but not tuberculated; secondly, those of the same form but with tubercles; and lastly, such as are like the last division, but with the spires turriculated. Eight species are described by Lamareck, one only being found in the Mediterranean, the others are principally from the Indian Seas; about the same number of fossil species are known.

**FERONIA** (Latreille). An extensive genus of coleopterous insects, belonging to the section *Pentamera* and family *Carabidae*, forming the type of one of the divisions of the sub-family *HARPALIDES*, which see.

**FERRARIA** (Linnæus). A genus of bulbous plants introduced into Europe from the Cape of Good Hope. Class and order *Monadelphia Triandria*, and natural order *Irideæ*. Generic character: flowers in a spathe: corolla in six oblong undulated

segments, the outer ones broadest; stamens, filaments joined to the tube; anthers rather egg-shaped, double, style filiform; stigmas three to six, pencil formed; capsule below three-celled. The *Ferrarias* bear beautiful flowers, and thrive in sandy loam; like *Iris*, they should be kept in a frame and perfectly dry when not growing, but regularly watered as soon as they present their leaves.

**FERULA** (Linnæus). This is the giant fennel of botanists, and consists chiefly of large coarse-looking herbs, found over all the northern parts of Asia and Europe. The genus belongs to the fifth class of sexual botany, and to the natural order *Umbelliferae*. Two of the species, viz. *Persica* and *assafetida*, yield the medicinal gum, known by the latter name. The plants are cultivated in Persia, whence the drug is exported to all other parts of the world.

**FESTUCA** (Linnæus). A genus of grass found in almost every quarter of the globe, and one of the most useful in pastures, particularly those for sheep. Twelve species are agricultural; and the pure seeds of most of them may be purchased at the shops of agricultural seedsmen.

**FICARIA** (Dillwyn), is a common weed found in damp woods. It is called pillwort, from the shape of its little bulbs, which lie on the surface of the ground, appearing like scattered grains of wheat. It belongs to the natural order *Ranunculaceæ*, and was considered a ranunculus by Linnæus.

**FICOIDEÆ**. This natural order contains all those plants known by the name of fig-mary-golds, or mid-day flowers, so denominated from their usual time of flowering. They are herbaceous plants or under shrubs, with opposite or alternate fleshy, simple leaves; of very curious and often grotesque forms, and destitute of stipules. The inflorescence is for the most part terminal, seldom axillary, and the flowers are regular and united. The sepals are definite, usually three in number, but varying from four to eight, more or less connate at the base, and either free or adherent to the germen. The

Ficoideæ.

petals mostly indefinite and often connate, sometimes five alternate with the sepals, and occasionally abortive when the inner part of the calyx is coloured. The stamens are indefinite and seated round the germen; filaments free; anthers oblong, incumbent,

two-celled, opening lengthwise. The ovarium is either free or adhering to the calyx, and consists of as many carpels as there are sepals. The styles are distinct and short, and the stigmata simple.

The fruit is a many-celled capsule, either free or encompassed by the fleshy calyx. When drupaceous, indehiscent: when dry, opening in a star-like manner from the apex; seeds indefinite, seldom definite, and very seldom solitary by abortion.

The flowers are generally beautiful, and the plants are great favourites with many cultivators. Upwards of 400 species are already known. The *M. crystallinum* is the common ice-plant, and *M. umbellatum* is extremely showy. They are all innocuous; and the succulent leaves of *M. edule*, *sesuvium*, *Portulacastrum*, *Tetragonia expansa*, &c. make excellent substitutes for summer spinach; and are used as such in South Africa. The *M. crystallinum* is called in Spain *Barilla moradera*, and is cultivated to a great extent for the purpose of procuring alkali for the glass-works; and in one year the exports of its ashes from the Canary Islands, amounted to 600,000 francs. *M. nudiflorum* grows wild in Egypt, and is there burned for the same purpose.

**FICUS** (Linnæus). A very extensive genus of lofty trees and shrubs, chiefly tropical. Linnæan class and order *Polygamia Diœcia*, and natural order *Urticææ*. Generic character: receptacle fleshy, closed, but permeable at top, androgynous; florets on footstalks, males three-parted; stamens three, females four, or eight-parted; styles laterally divided; seeds contained in the pulp of the receptacle. Only one (*F. carica*) of the many species yield eatable fruit, and which is the cultivated fig of our gardens. In the south of Europe figs are one of their most esteemed and valuable fruits, not only from their forming an article of diet in the season, but from their being an important article for exportation to other countries.

The fig-tree is remarkable for yielding, in its native country, two crops of ripe fruit in the course of twelve months. The young fruit which make their appearance in the autumn of one year, ripen in the beginning of summer in the next; and the fruit which show themselves in the spring, ripen in the following autumn. In this country the spring-produced fruit rarely or never ripen in the open air; but the autumn fruit, if they escape the frosts of winter, ripen perfectly, as well on standards as on walls.

No tree is more easily increased than the common fig; suckers which the tree produces in plenty, make good trees; it also strikes root readily from either layers or cuttings. Planted against walls, they are usually trained with branches diverging from the root like a fan; but they may be trained in any form. Standards in the open ground are trained in the round bush form.

The best soil for figs is a strongish hazel loam on a dry bottom, but they thrive in any good garden soil.

Much depends on pruning; the young shoots produced in the spring do not ripen fruit, but if these shoots be stopped by breaking off the point as soon as they are from four to six inches long, they will produce other shoots which will bear plentifully, and ripen fruit in the autumn of the next year. So that keeping the tree free from old branches and stopping the spring shoots every year, about midsummer, will keep a constant supply of bearing wood to be depended on. Large fig-trees on walls managed in this manner, are well worth defending from frost by woollen net-

ting, or some other temporary curtain, to be let down or put up when necessary. All the fruit produced on the spring shoots, and which never ripen, should be pulled off the tree in September, causing very frequently other young fruit to come forth on one or both sides of the place where the first grew. This second birth are sure to ripen in the following summer.

When hothouses are built for the cultivation of the fig in this country they are brought to very great perfection, not only as to quality and quantity at the usual and natural seasons, but for the advantage of having this fine fruit in every month of the year. And this resulted only from a little extra care in pruning, and the application of fire heat at the proper times when required. The native climate of the tree is imitated and maintained, so that its natural tendency to produce double crops is favoured and assisted; and indeed, if the tree be well nourished at the root, and kept in a high temperature, it proves an everlasting bearer. No fruit tree answers better in pots or tubs than the fig; and where there is a dozen or two of potted plants, and a hothouse or pit always in work, the manager may have ripe fruit at any time.

There are fourteen or more varieties cultivated at present in our gardens; a few of the best are as follow:—

Brown or chestnut-coloured Ischia.	Large Genoa.
Black Genoa.	Black Ischia.
Small white early.	Brown Italian.
Black Italian.	Brunswick.

**FIDDLE-WOOD** is the *Citharoxylum quadrangulare* of Linnæus, a genus of ornamental timber trees, chiefly natives of the West Indies, and belonging to the natural order *Verbenacææ*. These stove plants are easily propagated by cuttings struck in sand under a glass.

**FIELD CRICKET**, the *Acheta campestris*. See CRICKET.

**FIG TREE**. See FICUS.

**FILBERT** is the *Corylus avellana* of Linnæus. The name filbert is only applied to the improved varieties of the common hazel nut, of which there are eight or nine in cultivation. A few filbert trees are seen in every garden, but in the county of Kent fields of many acres are planted with them; and to the owners yield remunerating crops. Filbert trees are propagated by grafting it on the common hazel, or, what is better, by layers. When these are rooted, they are lined or bedded out in the nursery, and there trained up with one upright stem pruned clear of branches. When planted in their final stations, the stem is cut down to eighteen inches from the ground. This height will admit of a clear stem of twelve inches below, and which part must at first and ever afterward be kept free from shoots, as well as suckers from the root, which last the tree is very apt to produce. The deprivation of shoots and suckers will cause the buds left at the top to shoot with greater vigour. If eight strong shoots be produced in the first summer, they must be carefully preserved, as that number is required to form the head; but if less than this number come forth, then two or three of the strongest (or the whole if necessary) must be shortened back to half their length at the next pruning, in order to obtain the requisite number.

The full number being obtained, they are carefully preserved and trained outwards and upwards; at first nearly horizontal, but curving gradually upwards.

The easiest mode of doing this is by using a hoop of proper size placed within the shoots, and to which the latter are tied in star-like order, and at equal twelve-inch distances. Such a laterally curving position may be much assisted and caused by the pruner always cutting at an outside bud, which naturally grows first outward and then upward, and continued to the height of six feet, but never higher; and the middle of the tree is, in the mean time, kept free from shoots and branches, so that a well-trained head becomes at last like a large bowl or basin.

The subsequent management of the trees, both while gaining the desired form and after having gained it, consists in preserving all the short spurs produced on the branches, and shortening the small lateral shoots, which every year rise from the same. The management of these laterals is of great importance. If they exceed the length of six inches, they may be cut back to a few buds; but if less, they should be preserved entire, as their points are generally fruitful. The special object of the pruner is to have the branches thickly beset with fruitful spurs, and which are only reduced in length, when, after a few years' growth, they become too distant from the branch, when they are pruned back to a healthy spur at their base. If any part of a branch become accidentally naked, a strong shoot from the bottom may be led up, and managed so as to fill the vacancy.

When filbert trees are thus managed, and have arrived at their full volume in width and height, they may be kept in the same state for many years—say twenty or thirty—by the knife only, and with the requisite skill in using it. When the fruit are intended for long keeping, they should remain on the tree till thoroughly ripe, which is indicated by the rich brown colour of the shell. They require to be laid on a dry floor for a few days, and afterwards stored in jars of dry sand, where they, the kernels, will keep sound for a long time.

FILICES are the first order of the class *Foliaceæ*, in the second grand division *Cellulares*. This order includes all the ferns, of which there are fifty-three genera, and three hundred and eighty species. The

are minute, one-celled, brown, membranous, and surrounded by a thick articulated elastic ring, irregularly bursting, and either clustered on the lower surface of the frond, or compound in spikes. Their expansion is circinate, and some increase themselves by bulbs.

a. b. c. Frond and fructification of ferns.

The old botanists denied that ferns had seeds; but it is now proved beyond all doubt, that the fine dust shed by the fronds are really seeds.

Ferns delight in a humid soil, and they often grow parasitically upon trees. The medicinal virtues of some are highly astringent, others anthelmintic, or purgative; some are said to be pectoral, and others are valued for their corroborant qualities. The young leaves and roots of some are used as food; beer is brewed from the roots of others; and the fronds of *Aspidium fragrans* has been used as tea.

FIMBRIA. A genus of shells constituted by Megerle, but now classed with the genus *Lucina*, as being properly no other than one of its species. Cuvier, however, called it *Corbula*, but a more accurate examination of the species appears to confirm the propriety of referring these molluscs to the genus *Lucina*.

FINCH. (See FRINGILLIDÆ.)

FIORIN is the *Agrostes stolonifera* of Linnæus, a British grass, of which much noise was made some years ago by a Dr. Richardson of Ireland, who maintained that it was more valuable for green winter fodder than any other: that it was indestructible by rain or snow, and contained great fattening qualities. It has been extensively tried in other countries, but has not maintained the character first attributed to it as a winter fodder.

FIR, is the English name of the trees included in the genus *Abies* of Salusbury. The silver and spruce firs are the most common examples of this tribe of forest trees. Linnæus ranked them in his twenty-first class *Monæcia*, and tenth order *Monadelphia*, and they are among the most magnificent plants of the order *Conifera*.

The firs are almost all remarkable for the regularity of their growth, tapering form, and great altitude of their boles. Their timber is also excellent, and almost solely used in the construction of houses; being easily convertible, and withal durable, in consequence of the great quantity of resin it contains.

The hemlock spruce is one of the commonest trees of North America, and on the west coast of the middle parts of that continent, some of the firs grow to an amazing size and height.

All the varieties are raised from seed, and, after being transplanted two or three times in the nursery, are then fit to be planted out for good. For further particulars of this interesting genus, see *ABIES* and *CONIFERÆ*.

FIRE-FLY. A name indefinitely bestowed upon any winged luminous insect. The *Elater noctilucus* (see ELATERIDÆ); the *Fulgorea candelaria* and *lanternaria* (see FULGORA), and sometimes also the winged glow-worms (LAMPYRIDÆ, which see), being alike

a. b. c. d. Part of a frond and magnified capsules of ferns.

ferns of this, and other temperate regions, are comparatively humble plants, their true stems generally creeping on the surface of the earth, or subterranean; but in the West Indies, and other hot insular situations, arboreal species are found, the stems of which rise out of the earth, and elevate their crowns of fronds to the height of thirty or forty feet, or even more. In these noble examples of the class, the true structure of the stem, and affinities of the plants in general with the palms, is much more obvious, even to the common observer, than in the suffruticose and herbaceous brakes that are now indigenous to these northern latitudes. The fronds or leaves are usually pinnatifid, and more or less compound; sometimes nearly simple and entire, with reticulated veins. The capsules

described in popular works under this name, although some of them are beetles.

**FISH.** *Ichthos* is the Greek name for a fish, and from this, that branch of natural history which treats of fishes is called *Ichthyology*, which means "the voice of fishes," or the account which they can give of themselves, not in words, of course, for fishes are remarkable for their silence, but in such facts and relations as human observation can collect concerning them. Fishes form the fourth and last division of vertebrated animals in Cuvier's structural arrangement of the animal kingdom; and, from the length of time, and close and scrutinising attention which he bestowed upon this class of animals, his arrangement of them must be considered as perfect a model of a natural system as the whole mass of acquired knowledge, in the hands of probably the ablest and the most candid generaliser that ever devoted his talents to the promotion of the knowledge of nature, could afford; and it is well for the world that there was a Cuvier to give a scientific form to this department of natural history, and give to the makers of local discoveries a foundation upon which they can build with safety. The advantage of this in the class of fishes, above all other classes in the animal kingdom, must become apparent to any one who reflects for a moment on the field which the fishes occupy, and the powers with which they are endowed of increasing their numbers.

We need hardly mention, that, with few and casual exceptions, such as the march of an eel for a few yards over the meadow, or the passage of a flying fish for a few yards through the air, the fishes are all inhabitants of the waters; and though it is possible that the number of them in the fresh waters may not be much less than that of the land mammalia, or the land birds, yet this number, vast as it is, sinks into nothing when we turn our attention to the sea.

Any one who is in the least conversant with the elements of descriptive geography must be aware that the extent of the sea is much greater in mere surface than that of the land: that, if we reckon the whole surface of the globe, in round numbers, at two hundred millions of square miles, which is not very wide of the truth, the land occupies only about sixty millions of these, while the sea extends over one hundred and forty millions, or double the extent of the land, and a third over. This, however, is not all, nor nearly all, when we come to consider the capabilities of the two for being the abodes of life. In the first place, the land contains many portions, and those of considerable extent, which are permanently barren, and incapable of furnishing food for a single living creature, while many other parts of it are subject to periodical barrenness. The sea, on the other hand, contains no barren spot, for its waters are everywhere nearly the same both in composition and in degree of temperature; and thus, taking surface for surface, and considering the animals which are adapted for the two great component parts, it is the land which is comparatively the desert, while "the waste of waters," as it is sometimes called, is fertility all over. But, in the second place, even this is taking a view of the subject too favourable for the land, and therefore unjust to the productive powers of the sea. It is the surface of the land only which yields food for its inhabitants, or, at most, the trees and plants which grow out of it; and as there certainly is not a tree or plant

upon the face of the land answering to every hundred square feet, that is, to every square of ten feet, and rising to the height of one hundred feet, we may safely say that one foot of habitable depth is an ample allowance for the land. It is not, in fact, the tenth, or even the hundredth part of this; but we shall allow it to be one foot, and then let us proceed to compare its habitable and supporting extent with the habitable and supporting extent of the sea. To gauge the sea is out of the question, for it is rather a difficult task to gauge a mill-pond, if it be anything irregular in shape and depth; but those who have paid the most attention to such analogies as are attainable upon a subject so vastly great, have assigned to the whole of the sea an average depth of between four and five miles. Let us, however, take it at the depth at which fish have actually been caught, namely, fifty fathoms, or six hundred feet (and we are not warranted in saying that this is the lowest limit), and we have every mile of sea equal to six hundred miles of land, or the whole pasture of the fishes to that of the land animals as fourteen hundred to one. It is true, that the fishes which are taken at these great depths are peculiar—that they have great eyes like the owls and other nocturnal feeders among land animals, indicating a deficiency of light in their profound abode: but we know not the limit, even in the depth of the ocean, beyond which we are warranted in saying that there can be no living creature.

Such is the pasture which the Author of Nature has prepared for the fishes; and, in order that they may increase and multiply, so as to replenish this ample pasture, he has endowed them with reproductive powers of the most extraordinary character. Some of the land animals are no doubt very prolific, but the races which are so are very minute in their size, and the duration of their lives is brief, they being seasonal only on most parts of the land, and in most situations. Some of the most productive inhabitants of the sea are, on the other hand, of large dimensions, and, instead of being merely seasonal, as is the case with land animals of very numerous progeny, they not only last for years, but, as we shall show by and by, they do not contain in their structure that element of death which ultimately brings the most long-lived inhabitants of the land to mingle with its dust. As an instance, we may mention the common cod-fish, which contributes so largely and so wholesomely to the food of many nations, and which, notwithstanding the great number of hands employed in its capture, never appears one jot less plentiful. A single cod-fish produces, at one birth, as many as between three millions and four millions of young; while the common flounder produces not much less than a million and a half. These statements are well calculated to stagger the belief of any one who has not attended to the subject; but they are the results of actual observation in counting the number of eggs in the roe, by those who could have no earthly object in the matter other than the discovery of the truth. We have thrown out these hints in order to show how well worthy the finny tribes are of our most careful observation and study; and having done so, we shall proceed to give a brief general view of the class. In order to render this view as intelligible, and, at the same time, as complete as the narrow limits within which we must confine it will allow, we shall divide it into four parts or sections: first, the general structural definition of a fish; secondly, a

very brief notice of the different parts of its organisation; thirdly, a short notice of the distribution and habits of fish; and fourthly, an outline of Cuvier's arrangement.

**GENERAL DEFINITION.** Fishes are vertebrated animals, having a double circulation, and breathing air, but only through the medium of water; their circulation is slow, and their blood, though red, is cold. The heart of a fish consists only of one auricle and one ventricle, answering to the pulmonary or right side ones of the double heart in the mammalia and birds; and the function of this heart consists in receiving the blood from the body, and sending it to the breathing apparatus, just in the same manner as the right side of the double heart in the mammalia does.

The breathing apparatus is very different from that of animals which breathe the free air. These receive the air into the cellular tissue of the lungs, or into the separate cells arranged along the sides of the abdomen (as in insects), and the vessels in which the blood is subjected to the action of the air are ramified over the walls of these cells. The breathing apparatus of fishes are called gills; and in their most perfect state they consist of fringe-like appendages attached to the posterior sides of certain arches of bone, which are articulated to the *os hyoides*, situated on each side of the neck, and have their ingress always by the mouth of the fish, and their egress always in the neck, and capable of being opened and shut by means of an apparatus which, taken altogether, is called the *operculum*, or gill-lid. The fibres or leaflets of the gills have their surfaces closely ramified over with a very fine tissue of blood vessels, which consist in the one part of arteries, and in the other of veins, as in the lungs of animals which breathe free air, or not through the medium of water. A current of water runs constantly through between the arches, and bathes the fringes on all sides when the fish breathes. This current is always from the mouth to the gill-openings; it is promoted by the joint action of the two; and if any attempt is made to force a passage for the water in the opposite way, or from the gill-openings to the mouth, as if by holding the fish head downward with the gill-lids open, then the fish is drowned, as certainly and as speedily by water, as a land animal would be by being kept the same length of time below the surface of that fluid. As the current of water passes through the gills from the mouth to the gill-openings, the blood, which is contained in the small vessels, which are ramified over the fringes of the gills, receives the benefit of the air which the water contains, to the same effect, if not in the same manner, as the blood in the lungs of an animal which breathes the dry air upon land.

When the blood has thus passed through the gills, and undergone that renovating process, it is not conveyed back to the heart as in land animals with warm blood, because there is no arrangement on the left side of the heart to receive it. The blood which returns from the different fibres of the gills, is conveyed by veins, which gradually unite with each other into an arterial trunk, placed along the spine, in what may be considered as the safest part of the whole cavity of the fish; and this cavity answers the purpose of a left auricle in receiving the blood from the breathing apparatus, and also that of a left ventricle in distributing it all over the body, in so far as the peculiar structure of that body renders the distribution of blood neces-

sary. The quantity of blood contained in a fish is, however, much less in proportion to the size of the fish than that contained in the mammalia or the birds; and so much blood is not necessary, because the greater part of the muscles being articulated on the spine, and inserted in the skin of the fish, appear to require the application of blood at the one extremity only. Thus, if a flesh wound is made in the body of a fish, which does not reach so deep as to divide the muscles down to the spinal column, such a wound does not bleed; and, in so far as we can judge, the fish feels very trifling pain from it, in comparison to that which a similar wound causes to an animal with a double heart, and warm blood distributed throughout all parts of the body. This exemption from pain in the case of laceration of the flesh is a very beautiful contrivance in the economy of fishes. Most of the race are very voracious, and very indiscriminate feeders; and not a few bite and tear in cases where they are not capable of swallowing the object of their attack. As the fish, when below the surface, is liable to attacks of this kind in all directions, the defence of insensibility to wounds which do not reach a vital part, is of great service to it; and if we attentively examine the structure of this class of animals, and the texture and character of their different parts, we shall find that their adaptation to their element, and to the circumstances of that element, is equally perfect with that of any other living creatures.

In one respect, fishes bear a nearer resemblance to birds than they do to any other of the vertebrated classes, inasmuch as their progressive motion is through one element, without any thing more solid, or of greater specific gravity, which they can use as a fulcrum or starting point to their motions, as is done by walking animals. The chief difference in this respect is, that fishes have to make their way through a medium which is very nearly of the same specific gravity as their own bodies; and thus there is nothing, independently of their own motion, to make them either ascend or descend. Birds on the other hand make their way through a medium of much less specific gravity than even the lightest of them; and thus in their motions they have a double operation to perform,—they have to keep themselves up against the pressure of their own gravitation, and also to make their way progressively; the fish is absolved from the performance of the first of these operations; and thus it can concentrate the whole of its energy upon its progressive motion; and thus, though it has to make its way through a much denser medium, it probably does not require nearly so much exertion as the bird. Any one who examines the general forms of fishes will observe that, notwithstanding their almost endless differences, they are all adapted for getting easily through the water; and, while the feathers of birds are in many instances so constructed as to take an absolute hold on the air, almost all, if not all, fishes have the surface of the skin supplied with a mucous secretion, which prevents them from even being wetted so long as they are alive, so that a fish gets through the water with much less resistance of friction than a dead substance of the same form and weight; and it is worthy of remark, how much more difficult it is to pull the body of a fish through the water after this mucous substance has dried, than when the fish is instantly dead, and this substance is fresh and abundant. As fishes require no support against the pressure of their own weight, they stand in no need of wings like birds;

and, as they do not move from a fulcrum or point of rest more stable than the water, feet would be equally superfluous.

Accordingly, the motive powers of fishes are more exclusively concentrated upon the spinal column than those of any other vertebrated animals. Even the ophidian reptiles form no exception to this, though they are in general destitute even of the rudiments of feet; for, as they start from a solid support in the successive portions of their motion, they act against that support by means of the scales on the under parts of their bodies and their ribs, which may be considered as a sort of substitute for feet; and, though many of the ophidia can swim well, even those which are habitually aquatic have no proper swimming apparatus. (See the article *OPHIDIA*.)

Fishes have, generally speaking, rudiments of four extremities, two anterior and two posterior, answering to the fore and hind feet of the mammalia; but these are often wholly concealed within the skin, and sometimes they are altogether wanting, especially the posterior ones.

A fish which is considered of the most perfect or typical form, has all these four extremities more or less produced beyond the skin; and their extremities consist of membranous tissues more or less entire, and supported by a framework of rays, which are in some cases continuous spines, in others made up of a succession of articulations, and in many the two kinds of rays are united in the same organ. These terminations have a rude resemblance to the fingers and toes of the human subject, or to the toes on the fore and hind feet of the digitate or toed mammalia. Those rayed and membranous appendages are called *fins*, which is the general name for all the proper organs of swimming or progressive motion through the water. The fins, which answer to the fore feet of mammalia and the wings of birds, are from their situation called *pectoral fins*. They vary much in form and size in different species, being short, or hardly, or not at all, developed in some, but not so much produced in others, as to answer the purpose of a sort of wings, during a short flight, or rather leap, through the air. They are, however, less frequently wanting than the fins which answer to the hind feet. These last are called *ventral fins*: they vary much in their situations, being sometimes placed far back, at other times far forwards, so as to be under, or even in advance of the pectorals; and in other cases again they are in a medium situation. The position of ventral fins is a very good character, not merely for the external distinguishing of fishes, but as an indication of the style of their swimming, and this again leads to some knowledge of the nature of their haunts and habits.

The pectoral and ventral fins of fishes are not, properly speaking, organs of progressive motion in swimming through the water; but they are to keep the body in such a position as that the proper swimming organ can act with the greatest advantage, and they are also useful in the keeping or the altering of the course through the water.

The really efficient fin in progressive motion is the *caudal fin*, or that attached to the extremity of the vertebral column, or tail. This fin is always spread out in a kind of fan-shape, but its termination is very variously formed in different species; sometimes it is squared over, sometimes rounded, sometimes wedged-shaped, and sometimes forked; but it is always placed on the same plane with the elongated pro-

cesses of the spinal column, or in a position exactly crosswise to that of the fan-shaped tail in birds. This shows the difference of use in the two organs. The tail of the bird is chiefly useful in ascending and descending, contributing nothing to the progressive motion, and very little even to the direction of that motion.

Besides the pectoral and ventral fins answering to the four extremities of mammalia and birds, and the caudal fin, which though it occupies the position of the tail in the other classes of vertebrated animals, yet performs a far more important function than that organ in any of them, the fishes have, in very many species, other fins attached to the extremities of the mesial plane, or that plane which passes through the centre of the spinal column and its processes. These fins are attached to additional bones, which are generally articulated to the processes. Those which are on the back of the fish are called *dorsal*, or back fins, and those which are on the under part, and which are always in the rear of the cavity of the body, and of course of the vent, are called *anal fins*. The dorsal fin is sometimes single, sometimes double; and there are many species in which the dorsal and anal fins are joined to the caudal one, forming a sort of finny margin round a considerable part of the mesial plane of the body. In fact, to describe all the varieties of those fins would be to enter very largely into the detailed description of the species.

What may be considered as the natural position of a fish, that is, the position in which the greater number of them are placed, both when they are at rest and when they are in motion, is with the mesial plane vertical, or in the direction of the perpendicular. The dorsal, the anal, and the caudal fins, have always the direction of this plane; and therefore in a fish which has what we have called the natural position, those fins have their planes or flat sides laterally, and their thin edges in the direction of gravity. From this it is easy to see that neither of those fins can in this direction produce, or assist in producing, either an ascent or a descent of the fish, because their action is across the direction of gravity, and therefore it can neither directly assist nor directly oppose that force. They strike laterally, and as we may consider that when the fish gives its stroke, there is a certain portion of their body forwards, which keeps the direction in which the fish moves, without any deviation either to the right or the left, we may consider some point, either the centre of gravity of the fish, or some point very near it, through which if a perpendicular, or line in the mesial plane, be supposed to be drawn at right angles to the axis of the body, then this line will be the centre upon which the propelling portion of the body may be supposed to turn alternately to the right and left, just as a paddle does when it is worked right and left across the middle of a stern of a boat. It will also be apparent that the greater the mass and weight of the fish which is before this centre of motion, the progress of the whole will be the more steady.

But though there is this analogy between the action of the posterior part of a fish and a stern paddle in a boat, we must not suppose that there is any comparison of the two in point of efficiency. The boat has no general principle of union and consent with the paddle; and it very often happens that the one is the worse possibly adapted to the other than we can well imagine. The fish on the

other hand, is one complete structure, actuated by a single principle, and having all its parts adapted to each other with a perfection of scientific principle which it would be vain for man to attempt imitating, except at the most humble distance. The fish does not bend the posterior part of its body right and left upon a single point, but brings it to a curve by an immense number of vertebrae; and in many species the pieces composing this vertebral column are in themselves so flexible, that the support of the muscles, or that which is moved in the striking of the fish right and left as it swims, may be compared to an elastic rod. But there is also something farther and more beautiful in this piece of mechanism. The muscles, or moving forces, are placed in flakes attached to cartilaginous septa or divisions, which proceed in an oblique, and generally in a curved manner, from the vertebral column and its processes, to the skin on each side; and this succession of muscular flakes is continued, not only the whole length of the posterior part which we have supposed to have the chief motion in ordinary swimming, but from the base of the skull to the caudal fin. The individual fibres of those muscles are placed, generally speaking, in a longitudinal direction, and their contraction bends the whole fish in a graceful curve towards the contracting side; and in cases of great exertion this curve may become an entire semicircle, nay, almost an entire circle with the muzzle touching the extremity of the tail, as may often be seen in a salmon when it attempts to leap a cascade of considerable elevation; nor would one readily believe, without actually seeing it, the height to which the unbending of this curvature by the action of the muscles on the other side can project the fish. This leap is of course taken laterally through the air; and so must be the leap of every fish when it rises to a considerable height out of the water—that is to say, the fish must project itself “broadside on,” but it is very remarkable that when it falls in the water, a cat does not fall more certainly upon its feet than a fish falls in that attitude of the body which is natural to it in swimming. It is further not a little curious, that if the fish falls upon land or on a rock, it does not right itself in this manner, but rather alights on the side, as may be observed of leaping salmon when they fall on the banks, or of flying fishes when in their attempts to escape from their pursuers they alight on the decks of ships. The mechanical action of fishes is, however, a matter which has been but little investigated; and though from the variety, the freedom, the rapidity, and very often the gracefulness of their motions, it is a subject fraught with a vast deal of mechanical information, it is one which, however desirable it would be, we cannot for obvious reasons prosecute further in a popular work.

**PRINCIPAL ORGANS OF FISHES.**—We shall give very short notices of the principal systems of organisation in the finny tribes, and leave the reader to generalise them. They may be conveniently brought under the heads of support, protection, sensation, motion, adhesion, respiration, circulation, nourishment, and reproduction; for we may pass over the systems of absorption and secretion, and refer the electric powers which are possessed by certain fishes to the particular descriptions of the *Gymnotus*, the *Torpedo*, and the various other species which have this property.

*System of support.*—This system consists of bones,

as it does in the other vertebrated animals; but the bones are of a softer consistency. Even the hardest of those which properly form parts of the skeleton, are to a great extent cartilaginous, and thus flexible, while others contain very little salt of lime. This affords a good general division of fishes into two very distinct and well marked sub classes; bony fishes, or those which have the bones more or less firm, and cartilaginous fishes, which have the bones flexible.

It would be foreign to our purpose to enter into a minute description of the skeleton, or indeed of the anatomy of any part of the fishes, and the subject is by no means an easy one, even for those who devote their chief attention to the structure of animals. The skeleton is in general very complicated, though comparatively concentrated into one mass, as compared with that of land animals, but the greater number of the articulations or unions of the pieces are quite different from these; and it is only in the jaw-bones and the dorsal and anal fins that we meet with any thing that can, properly speaking, be called a joint, or which consists of the motion of one bone immediately upon another. In every other part of the skeleton, the two adjoining pieces of bone are united by a greater or smaller extent of cartilaginous substance; and it is the yielding of this substance which forms the bending of the articulation, so that there is in the joint itself a certain degree of tendency to spring back again when it is bent, without muscular exertion. In mammalia and birds, the state of repose is a certain degree of flexure in which the joints are relaxed, and can be moved to some extent either way by very little external force; but the repose of the fish implies perfect straightness in the spinal column, and there is no relaxing either way, because all the muscles are equally in a state of repose, and the joints are held in an even state by the action of the cartilage alone. There is, perhaps, no animal in which rest is so complete and perfectly without effort or pressure upon any part of the body more than another, as in a fish when it is motionless in the water. The specific gravity of that fluid is of course exactly equal to that of the reposing fish, otherwise the fish would either sink downwards or rise upwards; and the water presses equally upon it in every part, so that it is impossible to conceive a kind of suspension more favourable to perfect inaction or waste of the system in any way, and this perfect rest is probably one of the reasons why fishes are capable of so much exertion at other times, and also why they appear to have unlimited powers of growth and endurance.

In taking the simplest view possible of the skeleton of fishes, we may consider it as consisting of a cranium, a spine, and ribs, together with the bones that support the lateral, the dorsal, and the anal fins. The cranium, or bones of the head, has no investment but the skin, and therefore its form is easily seen. It often consists of a vast number of pieces, but these generally soon become soldered together. The head is, generally speaking, united to the vertebral column by a single tubercle, and it has very little motion; few of the osseous fishes have any vertebra which can be called a neck, but some have, as, for example, the common herring, in which there are four. In the cartilaginous fishes the vertebra of the neck are generally soldered into one general piece. In the rest of the column the dorsal and caudal vertebra are easily distinguished from each other, as the latter

have processes both upwards and downwards, something in the form of a double comb, while the former have only spinous processes on the dorsal edge, and lateral processes on each side, which form the commencement of the walls of the cavity of the fish, protect a great or systematic artery, and in those species which have the ribs generally attached to them, the section of this column is sometimes cylindrical, sometimes angular, and sometimes compressed or flattened in the direction of the mesial plane. In bony fishes, each vertebra is composed of two hollow cups, of a conical form, the cavities of which are filled with fibrous cartilage; and in many species this cartilage extends through the centre of the column in one continuous cord for its whole length. The spinal marrow is not, as in land animals, contained within the vertebral column, but lies along the upper side of it, passing through the bases of the dorsal processes, which are all double at their origin, and may generally be split for their whole length. When the cartilaginous substance which unites the vertebrae or pieces of the back bone is examined, it has the appearance of a series of concentric rings; and it has been alleged that the number of these answers to the number of years that the fish has lived, but of this there is no proof.

The ribs of fishes vary much; cartilaginous ones have no true ribs, and in the bony fishes they are simple, forked, or double. In the carp family they are flat, in the cod family round, and in the herring they are like bristles. The number of ribs, and also of vertebrae, are good characters in distinguishing the several species of fish.

Besides the parts already mentioned, the only portion which can be regarded as directly connected with the skeleton, is the bony structure of the shoulder, or that which supports the pectoral fins. These consist of the two arches which, in fishes that have regular gills, always support the posterior edges of them, and furnish a place of resistance against which the gill-lids close, as well as give security to the anterior part of the cavity of the body. When perfect, these arches are united at their under extremities by cartilage, and at their upper ones they are attached to the vertical column, to the posterior part of the cranium, or to both. To these arches are attached, not by regular joints but by cartilaginous unions, the bones of the pectoral fins, which usually consist of two pieces, answering to the arm and fore-arm, and some small bones at the extremities of the latter, which have some analogy to the bones of the wrist. To these last the rays of the pectoral fins are attached. The bones which support the dorsal and anal fins are generally detached pieces, included in the flesh, though in some instances the dorsal is joined to the processes of the spine, and more rarely the anal to the same. When the ventral fins are situated as far forward as the pectorals, or farther, they are connected with the same bones, sometimes through the medium of an imperfect sternum or breast bone. When the ventrals are situated farther in the rear, the bones to which they are attached are most commonly imbedded in the flesh, without any connexion with the vertebral column.

The bones of the head are so many and complicated, and they vary so much in different species, that they cannot easily be made the subject of popular description. The bones of the jaws are generally very distinct from those of the cranium, and admit of

separate motions, and there are peculiar bones in the pharynx at the back of the mouth. The bony arches which support the gills are attached at one extremity of the os hyoides. The gill-lid consists of several plates of thin bone, which, in the fishes which have free gills, have a good deal of motion, and by expelling the water when they close, not only perform an office in respiration similar that of the raising of the diaphragm in the mammalia, but also, by the force with which they throw the ejected water backwards, assist in the progressive motion of the fish.

We have already mentioned that the bones of fishes are, generally speaking, of more flexible consistency than those of land animals, and contain proportionally less of the salts of lime. Their base of animal matter is different from that of the mammalia, as it does not appear that they contain much, if any, gelatine. Their composition has not been determined by any very accurate analysis; but it should seem that they are so far intermediate between the bones of land animals and insects, such as those of crabs and lobsters, for they contain a portion of subcarbonate of lime as well as of phosphate, only the quantity of the latter is more abundant. The bones of some fishes undergo a very remarkable change of colour when they are boiled; thus the bones of the blenny become green, or rather, perhaps, they are green without any boiling, as is the case with those of the gar-fish (*Belone*), which has also often been alleged to turn grass green in boiling, whereas it is green whether boiled or not, only the bones of fishes are seldom objects of common observation till they are boiled.

*Protecting organs.* Under this name we do not mean to include only those means of defence which fish have against their enemies; but their general means of protection against the macerating influence of the element in which they live. These may be divided into the three distinct processes of skin, scales, and spines.

The skin consists of three distinct parts, a true skin immediately over the muscles, a mucous tissue, and an epidermis or cuticle. In those species which have no scales, or very small ones, the true skin is often very thick, while in those which have the scales large it is often a very thin membrane. It adheres much more closely to the flesh than in any other of the vertebrate animals. When thick it contains a great quantity of gelatine, and as such it is useful as food, as glue or size, and for many other purposes. The skins of the cod and eel are instances. The skins of fishes have none of those villi or papillae which are found on the skins of the land vertebrata, and which are generally supposed to be organs of a sense of touch, and hence it has been supposed that fishes have little feeling of this sense. This is, however, to a very great extent hypothetical; for even in land animals these papillae are by no means the most delicate organs of this supposed sense of touch, for they are in all probability excelled by the whiskers of nocturnal beasts of prey, the margins of the wings of bats, and the fine and filmy terminations of the feathers of nocturnal birds. It is very doubtful if there be any such thing as an organ of touch *per se* in any part of the integuments in any animal; and the more rational view of the case is that the feeling is in the muscle, and the only office which the external integument performs is that of readily transmitting to that any impression made on itself. Every schoolboy who

has access to the smaller streams inhabited by trout, knows that if a trout under the bank be tickled, it will press against the hand as if very much pleased with the operation; and that if tickled sufficiently it may be lifted out of the water without offering any resistance.

The mucous tissue is understood to be the seat of colour in all animals; and in the fishes it is remarkable for its brilliant tints and iridescent reflections, the finest of which in general fade, when the fish is dead, and this tissue becomes dry and rigid. The epidermis is very soft in fishes, and very generally covered with a mucous secretion. It extends to the scales as well as to those parts that have none, and it also moistens the shells of aquatic mollusca in the living state. In fishes it appears to be seasonal, as it often comes off in patches of considerable size, when there is no reason to think that the fish is unhealthy.

The scales of fishes are placed on the epidermis, or rather they consist of thin tissues of epidermis with layers of phosphate of lime between, and it is to this structure that they owe their fine pearly lustre. Generally speaking they are imbricated, or placed over each other like the tiles on a roof, with their posterior margins free and generally rounded, and often with a fringed margin. When they are examined by means of a powerful magnifier, they show a very beautiful ramification of striæ, or little threads. When the fishes are in fine condition, and especially toward the season of reproduction, there is a beautiful bloom and metallic lustre on the scales, in the same manner as there is on the feathers of many birds; but when the season of reproduction is over, and the fish are exhausted, as they always are upon these occasions, the bloom goes off, and the surface is dull and lustreless. The fish are unwholesome when this is the case, and the rich and pearly lustre of the scales is one of the surest signs of the fish being in season, equally sure as the bright red of the gills is that it has not been too long kept. This is remarkably the case with salmon, the pearly hue of which is very rich when they first enter the estuaries of the rivers, but it wears off; and when they have spawned they are vernacularly termed "black fish," in which state the capture of them is prohibited, though poachers do sometimes take them, then and sell them at no small hazard to the lives or at all events the health of the purchasers.

In many species there are osseous plates, or tubercles, or spines, instead of scales; and where these occur they have always more the consistency of hard bone than the internal skeleton of the animals; nor is it unworthy of remark, that these bony appendages to the skin are, generally speaking, more general among the cartilaginous fishes, than among those that have harder skeletons. The sturgeons have the surface of the body studded with osseous plates resembling limpet shells; the sharks have it granulated with tubercles; and many of the rays have it beset with very hard and sharp hooked spines resembling teeth; and all these are cartilaginous fishes, with little or no hard matter in their internal bones.

It is farther worthy of remark, that this tendency to accumulate the salts of lime in the form of scales, plates, tubercles, and should accompanies the formation of gelatine, which, though found in very small quantity or not at all in the bones, exists in vast quantity in the skin; so much so that our best glue and finest jelly are obtained from the membranes of

fish. Nor is there any doubt that if the trimmings of the fins of fish, which are thrown away in such quantities, were collected and prepared by the removal of the fatty matter (which is chiefly *elaine* or oil fat, and might also be turned to valuable account) and the other foreign substances, a great quantity of an article very wholesome and nutritious as food, and very useful in many of the arts, might be recovered at little cost from absolute waste.

The protecting substances which we have now mentioned, do not appear to be in any case intended as direct defences against enemies; but they, the scales especially, answer some very important purposes in the action of the fishes; and it is worthy of remark, that those fishes which have not imbricated scales with their margins free, are either more long and flexible, or their fins more expanded, so that they are less active in swimming than those which have freer edged scales. The size of the individual scales does not appear to be a matter of much importance, so that the edges are free, because upon an equal extent of surface small scales are probably as advantageous as large ones.

The action of the edges of the scales is this: when the fish bends the body strongly to one side in the act of swimming, the force of the stroke would throw the head in the other direction, and a certain portion of the effort would be expended in actually driving the fish back; and this counteracting portion would always be the greater fraction of the whole, the more powerful the stroke, or, which is the same thing, the greater the flexure of the body. But when the fish is covered with scales, the posterior edges of which are free, any flexure or stroke of the tail toward one side must cause a proportional rising of the edges of the scales on the other, and the edges thus raised must each lay hold of the water, and not only prevent motion backwards, but give considerable effect to the stroke.

But besides these which we have mentioned, there are other spinous appendages to the coverings of fish which are of a more formidable character, and which may be regarded in the light either of offensive or defensive weapons. These have rather the form of spines, very sharp at the points, by means of which punctured wounds can be given, and they are often finely granulated over their surfaces, so that while they penetrate they lacerate like a file, and the wound is of a cankering and festering character; so much so that there is a belief that some of these species are poisonous, as is alleged of the spine of the dorsal fin in the dragon weever, *Trachinas draco*. That poison should be secreted on a spine in the fin of a fish, subjected to constant washing in the sea, and without the least vestige of a poisoning apparatus, which is always very complete and apparent in those animals which are known to inflict poison, would be rather singular; and though it is the general belief among those who receive wounds from these fish, there does not appear to be any more truth in it than there was in the old story of the deer poisoning those that were wounded by his antlers. It seems to be nothing more than a ragged wound which is inflicted in those cases, and we know that such a wound given by a steel instrument will often produce the most serious consequences.

These spines are placed in different parts of the body in different fishes. In the fins on the sides of the tail, on those of the head, on the gill lid, on the

shoulder, and on various other places; and when a large spine of this description is observed upon any part of a fish, it is always prudent to keep out of the way of it, so long as the fish is alive, as no animal, either of the sea or the land, is ever furnished by nature with a weapon without being at the same time endowed with the faculty of using it in the most effective manner. Even the lesser weever, which is a little thing about five inches long, will strike upwards, or right and left, and inflict very painful wounds with the spine of its dorsal fin, small as it is.

*Organs of motion.*—We have already alluded to this, both in the fins and in the muscles by which these are put in motion; we shall therefore merely make one or two general remarks here. Every one who examines the muscular structure of a fish, and observes that each side of the whole body, from the nape to the tail fin, consists of a rough mass of muscle, cannot fail to perceive the great advantage that arises from the division of this mass into so many different flakes, each of which is really a separate and independent muscle, receiving its own nerves and vessels from the spinal column without being in the least dependent on the others, and yet all of which can act miscellaneously and in concert whenever such action is necessary. So also, in consequence of this division of the mass into independent short lengths, the greater part of the fish may become not a paddle merely, with the fin on the tail, but an action something analogous to that of a many-oared cutter, striking right and left at the same time, and thus making the way of the animal in a perfectly straight line, while it is apparently turning along like a corkscrew. We have a very neat example of this in the common eel, the motions of which are close, but performed apparently in the most smooth and easy manner imaginable, and with the least possible fatigue. Then if there is a cross current to contend with, or anything else that causes more resistance on the one side than on the other, the greater power of the action can instantly be thrown where the greater effort is required, and the fish can keep its course without drifting, where any other creature would be completely at the mercy of the current.

Nor must we overlook the advantage of this accumulation of muscles in the event of any local injury taking place. The limbs of mammalia, and the wings of birds, are in their several articulations dependent on few muscles, and those of the one joint do not assist those of the other, so that if one is rendered unserviceable the whole limb is crippled. But in the compound muscle of a fish, though one or more of the flakes happen to be deeply wounded, there are still many others performing the very same office, and thus a very severe wound in one place will not greatly lessen the swimming power. This is of great service to fishes as a protection against each other. As is usually said, the fishes "care not a rush for the weather, but make themselves happy in eating one another whether it is foul or fair." Now this is very nearly, if not altogether, the literal fact of the case; and so, when numbers of them are congregated together in one place, and the shoals often amount to many millions, numbers of them must be constantly getting bites; and if they were as much affected as land animals are when bitten or torn, the sea would literally be enumbered with crippled fish. Anglers often catch a trout or a salmon which probably an otter has made pay the forfeit of nearly a

pound of flesh, and yet, with a great notch in his back, if it does not reach down nearly to the spinal cord, a fish will take the bait, or rise to the fly with nearly the same alacrity as if his skin was whole.

There is one other consideration worthy of notice with regard to the general condition of the organs of motion in fishes. They have really less work to do than the organs of any other animals, not excepting their neighbours of the deep. The crustacea have a dead weight to carry; and, in the case of a crab or a lobster, this dead weight forms no small fraction of the whole. So also the shelled mollusca have often to carry about five times their own weight in the house which they make for themselves; and this house is always specifically heavier than sea water, so that those which rise to the surface require a particular apparatus for floating it upwards. Land animals have also their own weight to carry; which, making allowance for difference of structure, appears to be almost equally laborious in those which walk and those which fly. But a fish has no weight to carry; for though, of course, the total pressure of the water increases with the depth, the specific gravity varies but little, because water is not much compressible; and from what we experience ourselves when exposed to different degrees of atmospheric pressure, we can readily understand that a fish may be as comfortable under the pressure of a hundred atmospheres of water, as a land animal is under that of the light atmosphere of a mountain top. Thus the only exertion which a fish requires to make is that which conducts it from place to place, either in search of its food, or on those journeys which many fishes perform seasonally, chiefly with a view to breeding. This appears to be the reason why fishes have so few blood vessels in the muscular parts of their bodies. From what we know of circulation, we may safely conclude that the waste of the system, or of any part of the system, is in proportion to the number of blood vessels, and the quantity of blood which circulates through them. Now birds, and especially mammalia, have those vessels so completely ramified through every part of their bodies, except the solid bones (and there is blood in various bones of the mammalia when young), the tendons and the simple membranes, that no part of their system can be lacerated, or even scratched, without the effusion of blood, for the skin itself is full of blood vessels; but before red blood can be obtained from a fish, the wound must be a pretty deep one, unless it is given through the tissue of the gills, through which the blood passes. We have already mentioned the names and situations of the principal fins; and so we have only to say a few words upon the difference of position in the abdominal ones, which are those that most differ in position; and this is all that is necessary to be attended to in a general glance, because the relative shape and degree of development in the different fins properly form part of the particular descriptions of the races. Now, in those species which have the ventral fins placed backwards, we generally find that the usual line of motion in swimming is nearly horizontal; and, in proportion as the ventral fins are brought farther and farther forward, the fish in its habit has more occasion to exert itself in raising the head upward when it moves from place to place. In general, too, those fishes which have the ventral fins far backwards, have the body spindle-shaped, and the head not very large; whereas those which have these fins brought so far forward as to be connected with

the same arches of bone which support the pectorals, have the head large, and the whole of the anterior part of the body thick and heavy, as compared with the posterior. Some fishes are, no doubt, of such odd shapes, and have so many extended filaments, and other curious appendages, of which nobody knows the use, attached to different parts of their bodies, that we are unable to apply any of the principles of our mechanics of simple forms to their singular structures; but still we find that, whenever the form of the fish is so simple that we can deal with it as we would do with a common mathematical solid, we find that the above stated principle applies; and that, whenever the ventral fins are brought forward near the throat, in aid of the pectorals, the anterior end of the fish is always the heaviest, and requires this additional apparatus for the purpose of lifting it up. The plenyopterose fins are at right angles to the axis of the body; and thus, while the posterior or progressively moving part impels the fish forward, the accumulated fins under and on the sides of the throat, strike downwards against the water, and thus give an upward motion to the anterior part of the body. Fishes which have this enlargement of the head, and condensation of the lateral or cross fins near it, are, generally speaking, ground feeders; and, when they are feeding, hang at an angle with their heads lower than the hinder parts of their bodies; and, in this way, pick up molluscs, and other small ground animals. Those fishes which are altogether without ventral fins, and which are sometimes styled *apodal*, or footless fishes, generally remain quietly at the bottom, and seldom approach the surface. They are all of the *anguilliforme* or eel shape, with lengthened and slender bodies, and the pectoral fins close to the head, and generally lower down than in those fishes which have ventral fins under the pectorals. The use of these pectoral fins, which are in general pretty much produced, is to guide the head in any direction, upwards, downwards, or laterally, and not chiefly for the purpose of raising it, as in those which have the two sets of fins concentrated together near the same point. In most fishes the motion in advance is not produced so much by the stroke of the caudal fin as by the contrary throws of the posterior part of the lengthened body; and in order that that may be a more effective swimming apparatus throughout its whole length, the dorsal and anal fins are, in general, continuous, and meet at the extremity of the tail, where they in general form a rounded or pointed terminal fin.

Though ground fishes, those which have this structure are not exclusively, or even generally, ground feeders. They range the waters near the bottom, but they range them in line, and feed upon that which moves in the water, rather than that which is quiescent at the bottom.

The principle now stated, and it is a very interesting one, in what may be styled the mechanism of fishes (one of the most interesting branches of natural mechanics, because it presents us with motion directed only against one resistance, that of the water), cannot be better illustrated than by a reference to Cuvier's division of the *Malacopterygii*, or fishes with soft or jointed rays to their fins; and this allusion will at the same time show the beauty of the systematic arrangement, by that matchless adept in knowledge of the structure and functions of animals.

Cuvier divides this class into three families:—*Abdominales*, or those which have the abdominal or

posterior pair of fins placed backwards; *Subbrachia*, or those which have the second pair of fins placed forwards, either immediately under the pectoral fins, or sometimes in advance of them; and *Apoda*, or those in which the ventral fins are wanting. The tribes of fishes which come under the first of these families are the *Cyprinidae* or carp family, the *Esocæ* or pike family, the *Siluridae*, the salmon tribe, and the herrings and allied species. All of these are straight-forward swimmers, and the greater number of them are found near the surface of the water. They are, generally speaking, what we are accustomed to call handsomely proportioned fishes, rather long than otherwise, and, generally speaking, they are rapid in their progressive motions, and not remarkable for the facility with which they can plunge to great depths, or rise from them.

The second family, or those which have the ventral fins concentrated near the pectorals, and, generally speaking, articulated to or connected with the bones of the shoulder, comprehend the cod family in all its genera; the flat fishes, or different species of flounders, soles, turbot, and other genera and species of that type; and the *discoboli*, or those fishes which have the ventral fins formed into a sort of round disc on the under part of the body. All these are bank fishes to some extent or other, or if they are not found on banks of sand or mud, they frequent rocky places; and, generally speaking, feed near the bottom. In most of the species they are not very discursive, but remain on the same grounds, often accumulating in vast numbers; and one of the chief uses of the concentration of the four lateral fins at the anterior part of the body appears to be, to enable them to get over the inequalities of that bottom over which they find their food. The flat fishes deserve perhaps a particular notice on account of the particular position of their bodies when swimming, which is really with the side uppermost, and not the back, though the upper surface is coloured like the backs of ordinary fishes, and the under surface like the belly. There, is, however, a twist at the insertion of the head, which gives a very peculiar appearance to that part of this tribe of fishes; but it will be better to notice their general characters in a separate article *FLAT-FISH*, than to break the chain of illustration in the present one, or extend it to greater length.

The third, or apodal family of this order, consists entirely of elongated or eel-shaped fishes, which, like the former are ground-fishes, and perhaps upon the whole remain constantly nearer the ground than they; but they swim by contrary flexures of the body, and not by the stroke of the tail, as an eel. There is sometimes a vulgar prejudice against this class of fishes, in consequence of their snake-like form, and snake-like movements. The slightest attention will, however, suffice to convince any one that their motions are those of true fishes, and not of ophidian reptiles, even aquatic ones. The motion of these reptiles is always in the vertical plane, so that, even when they swim, the flexures or bendings of the body are upwards and downwards. Those of the apodal fishes, even of the most snake-like of them, are, on the other hand, always lateral, and they have little or no power of bending the body in the direction of the mesial plane, that is, in the direction of the edge of this plane. In passing we may here remark, that the curved form given by painters to their imaginary dolphin is perfectly inconsistent

with the mechanical structure of a fish; and that however a fish may be able to bend itself laterally, or even obliquely, there is no provision in the muscular structure of any one fish, by means of which it is able to bend the spinal column either upwards or downwards. The bending of flat fish toward the pale coloured side especially, must not be considered as an exception to this; for the flat fishes, as we have said, swim on their side; and the finned margins of their disc are as truly the middle of the back and middle of the belly marking the terminations of the mesial plane, as if they swam with that plane in the vertical direction and not in the horizontal. These few remarks must suffice in the meantime, for the various motions of the different fishes are so curious, and involve so many points in mechanics, that if we were to allow ourselves to get entangled in the details, there would really be no end. The subject is simple however, and as, in addition to this, it is highly instructive as a mechanical subject, it is eminently deserving of every reader's most careful attention and most diligent study.

*Organs of adhesion.*—The consideration of this branch will not detain us long. Fishes, generally speaking, have no apparatus, excepting the mouth, by means of which they can take hold of any one substance, and therefore, excepting in so far as they can counteract by means of their swimming apparatus, they may be said to be at the mercy of the waves. That apparatus is, however, so efficient; and the waves produced by surface agitations reach to so very small depths in the sea, that, generally speaking, the fishes may be said to be perfectly independent of them, except some of the lighter surface fishes, and the small fry which are occasionally caught in storms, and stranded on the shores in countless numbers.

There are, however, countless fishes which, from the peculiar places in which they seek their food, and the peculiarity of that food itself, have to hold on in the strength of currents, which would be too much for the fins of even the strongest and best formed of the finny tribes; and those species to which nature has assigned this habit, have of course received an adequate means of adapting themselves to it. The apparatus used for this purpose is a sucker, or cartilaginous disc, which this fish can apply so firmly to the surface of any solid object, fixed or floating, as that no action of the water can detach it. This sucker, when it is a mere means of stability, is placed either on the head or the thorax. In the remora, which has been so long celebrated, and of which so many ridiculous stories have been told, and of which as a genus, some account will be found in the article *ECHENIS*, the sucker is of an oval form, and consists of transverse rows of cartilaginous plates connected by one edge to the surface of the head, and in the other edge free, and finely pectinated. A longitudinal partition divides the plates in the middle of the head, and in the spaces between the plates, and on each side of the partition, a row of fleshy tubercles may be observed. In the cyclopteri this organ is of a circular form, and consists of numerous soft papillae. It is situated on the thorax. Instead of a separate organ of adhesion, the ventral fins in the goby are united, and are capable of adhering to rocks and stones, while in the lamprey the mouth contracts and acts as a sucker. All the species which have suckers of this kind for the purposes of mere adhesion, whether those suckers are placed on the upper or the

under part of the body, belong to the subbrachian family of the soft-finned fishes. They are generally, if not all, fishes of feeble powers; but the sucker enables them to adhere to rocks over or under them, according as it is at the top of the head or under the body; and while they so adhere, secure against the current, they are enabled to capture for their subsistence the fry of fishes, and other small animals which the current carries along. Of course they are not found in the placid waters, where this apparatus would be of no service to them, but chiefly in passages among rocks, through which currents set with much rapidity.

Some of the cartilaginous fishes are also furnished with suckers; but the suckers which they possess are placed on another part of the body; and generally speaking, calculated for other purposes. They are on the mouth, as in the lamprey, the pride, the hag, and some varieties; and though these are found at least in some of the species, occasionally adhering to stones with great firmness, yet the principal use of the sucker appears to consist in enabling them to extract their subsistence from the bodies of animals to which they adhere; and among them the hag, which is in appearance little else than a gelatinous sac, often sucks the substance of cod and other fishes while they are fast on the hooks of the fisherman's lines. See the article *MYXINE*.

*Respiration and Circulation.*—Both the organs and the process in these have been mentioned in the general preliminary remarks, so that it remains only to notice the differences which are found in different kinds of fishes. The respiratory organs are perhaps to be regarded as the most perfect and typical of a fish, when the gills are distinct upon the bony arches and face, and the gill openings ample and furnished with the most complete apparatus in the gill-lid. This part of the apparatus is sometimes wanting, but the gills themselves never are. When it is most complete, then is the gill-lid itself placed on each side of the head immediately behind the eye, articulated to the bones of the head, and shutting in the rear against the bony side of the shoulder, especially the large bone which answers to the humerus; and the lower extremities of both of which are riveted by a fleshy cartilage, and a similar substance ties them to the os hyoides; thus uniting the parts against which the gill-lids close with those to which both they and the gills are attached. This gill-lid is, in its external texture, either scaly, or membranous, or bony, and it is sometimes furnished with one or more hard tubercles or spines. Internally, it always consists of thin and flexible plates of bone, composed of a greater or small number of pieces in different places. When it consists of many, the one next the head, which is often double, is called the *pre-opercule*, the one behind that, toward the upper part, the *opercule*, below that there is the *subopercule*, and between this last and the extremity of the os hyoides, the *inter-opercule*. The posterior margin of the gill-lid, including under that name all the pieces above enumerated, or as many of them as may exist in the species, is variously toothed, though sometimes it is plain. In the greater number of fishes it is furnished with a fin-like appendage, called the gill-flap, which is supposed to contribute in some way or other to the action of the lid itself, and consequently to the breathing of the fish.

Count Lacépède founded a good deal of the clas-

sification of fishes, upon the form of this organ, but the classification has not been followed by more scientific and discerning ichthyologists; and indeed the breathing apparatus, especially in its more minute variations, is but ill calculated for being the foundation of any arrangement. In the distinguishing of species it may, like the number of rays in the fins, and of vertebrae in the spine, be of some use, because we believe it is pretty constant in the same species; but it is so obviously a character which leads to nothing, that it cannot be made the basis of anything more general in an arrangement which professes to assist in the study of fishes. All fishes breathe atmospheric air, and they effect this through the medium of water, the quantity of which is in all cases very much greater than that of the air, and it is every where very much the same. So that the character of the breathing apparatus is to be inferred from the habit of the fish, rather than the habit from the peculiar structure of the apparatus; and even when taken in this way there is not much in the inference. Thus, for instance, the eel and other apodal fishes, which move about at or near the bottom of the waters, generally have the gill-openings very small, and are without a gill-flap, a gill-lid, or both; while cod and many other bank fishes, which feed at the bottom, have the gill-openings unusually large, and the lids furnished with flaps. The number of rays in the gill flap, which are technically called "branchiapterygous rays," are, however, admitted into the list of characters in the subordinate divisions.

In fishes which have free gills, inserted upon arches of bone attached to the os hyoides, there are usually eight, four on each side, answering symmetrically to each other, both in form and in magnitude; but in some there is an additional small gill on each side, though it does not appear that any inference can be drawn from this as to the general habits of the fish, for it occurs in the herring, which is a surface fish, and also in the sole, which is a bank or ground one. The upper ends of the gill arches are attached through the os hyoides to the general mass of bones in the head, the under ends are attached to the bones of the tongue. The motion of that organ of course moves the arches, and they are besides flexible through their whole length. The anterior edges of the arches toward the mouth are covered with the same kind of integument as the rest of that cavity; they are generally more or less tuberculated; and in many species they are beset with teeth, and assist in the operation of conveying the food to the stomach.

In the *Chondropterygii*, or cartilaginous fishes, the gills are much less perfect. They are fixed to partitions, which answer nearly the same purpose as the arches of bone in the other fishes; but the fibres are very similar to those in the others, which shows that though the apparatus is different in form and arrangement, the operation to be performed is substantially the same. Some general notice of the structure of these fishes will be found upon looking back to the article *CHONDROPTERYGII*; but as the subject is rather a curious one, we shall add the details of some of the species as given by sir Everard Home. "In the lamprey," says sir Everard, "the organs of respiration have seven external openings on each side of the animal; these lead into the same number of separate oval bags, placed horizontally, the inner membrane of which is constructed like that of the gills in fishes. There is an equal number of

internal openings leading into a tube, the lower end of which is closed, and the upper terminates by a fringed edge in the oesophagus. These bags are contained in separate cavities, and enclosed in a thorax resembling that of land animals, only composed of cartilages instead of ribs, and the pericardium, which is also cartilaginous, is fitted to its lower extremity like a diaphragm." In the bag, or myxine, there are only two external openings, one on each side; but there are on each side six lateral bags, to each of which there passes a tube from the externa opening: and close to the left external opening there is also a tube which passes to the gullet, and forms a communication with the mouth. In the common chondropterygii which have their mouths of similar construction to those of the bony fishes, and which seize and swallow their prey, it may be presumed that the ordinary mode of breathing resembles that of other fishes, that the water is partially at least received by the mouth, and discharged by the gill-openings; and the communication which there is between the gills and the gullet in the lamprey and the myxine shows that they also, occasionally at least, receive water in the same manner. But the lamprey occasionally, and the myxine habitually, in feeding, adheres by the mouth as a sucker; and when this takes place of course neither air nor water can enter by that orifice; and thus the whole operation must be performed by means of the bags or cells, to the walls of which the fibres of the gills are attached. Hence there must be in this apparatus, a means of receiving and discharging the water, independently of all action of the mouth; and it is worthy of remark that in this respect those fishes bear no inconsiderable resemblance to insects which breathe wholly through apertures in the sides, which have no communication whatever with the mouth. The method in which this operation is performed, in the lamprey and myxine, is thus described by sir Everard Home:—"In the lamprey, the water is received by the lateral openings of the animal into the bags which perform the office of gills, and passes out by the same opening; the form of the cavities being fitted to allow the water to go in at one side, pass round the projecting parts, and out at the other. A part of the water escapes into the middle tube, and from thence either passes into the other bags, or out at the upper end into the oesophagus. There is a common opinion that the water is thrown out of the nostril: this, however, is unfounded, as the nostril has no communication with the mouth. In the myxine, the elasticity of the two tubes and the bags into which they open, admits of the water being received; and the pressure produced by the action of the external muscles forces it into the oesophagus, from whence it is thrown out by the opening at the lower end of that tube.

This operation appears to be performed by means of the cartilaginous ridges which are attached to the skin between the gill-openings. When the water is to be received, these arches are extended outwards, like a bow, by their extremities being moved by particular muscles; and thus cavities are formed, and as instantly filled by the pressure of the water. When this water has remained for the requisite time the ridges are unbent and drawn inwards, and the water is expelled; and this operation being repeated, constitutes the process of breathing in those peculiar fishes, altogether independently of the mouth.

In the ordinary breathing of fishes by the mouth, it

must not be supposed that the process, even in the mechanical application of the water to the gills, consists of a mere current, running without intermission in at the mouth, and out at the gill openings; for, as the separation of oxygen from nitrogen in the free air received into the lungs of land animals, requires some time for its performance, we may naturally conclude that more time will be required for performing the double operation of separating the air from the water, and then the oxygen from the nitrogen. This is also an operation which the fish can suspend at pleasure for a short time; but in the generality of fishes this time is very short. There is also rather a complicated operation of the mouth, which aids the current of the water when breathing. There is a sort of double mouth, the inner portion of which (which in many fishes is pretty far back) shuts, and shuts close on the anterior edges of the gill arches, so that when the gill-lid, or flap, or whatever it may be, is pressed down, the water, which has been wholly exhausted of its air, and is, therefore, unfit for the purpose of respiration, is wholly expelled from the gills, and as soon as this inner gate of the mouth is opened, and the gills expanded, fresh and wholesome water is admitted.

In ordinary fishes, there is no return by the mouth of the water which has once been received by the gills, and any thing which prevents the discharge through their openings, is just as fatal to the fish as if the supply by the mouth were excluded. If the ejection of the water from the gills of a fish be prevented, by the gill-cover being tied down with a string, it soon expires in convulsions. Similar fatal consequences follow when fish are placed in water previously deprived of its atmospheric air by boiling or freezing: and when fish are kept in a small pond, whose surface is frozen over, and where the water in that case cannot obtain a fresh supply of air, they speedily perish. If a small opening be made in the ice, before it be too late, the fishes will come near it for a fresh supply. In this manner fishes are frequently taken during winter in ponds and lakes. The extent of surface presented by the gills of a fish, to enable the blood to come in contact with the air in the water, is much greater than one would, without attentive consideration, be led to suppose. Dr. Monro calculated, that the whole gills of a large skate presented a surface equal to two thousand two hundred and fifty square inches, or equal to the whole external surface of the human body. The process of respiration for the supply of the gills is carried on even during sleep. The number of respirations in a minute is seldom above thirty, or below twenty. In the same individual it is liable to considerable variation, depending on the will of the animal. The blood, after being renovated in the gills, is re-absorbed by a multitude of minute vessels, which unite together; but, instead of returning the blood to the heart again, to be afterwards distributed through the body, this aorta exercises that function, and descends along the inferior side of the spine, in a canal fitted for its reception, giving off arteries during its course, to the adjacent parts. The blood is absorbed again by veins, which have extremely thin coats. These are much larger in their course than at their termination; and besides form, in different parts of their course, considerable receptacles for blood. Any injury received by the gills of fishes is attended with much pain, and a considerable effusion of blood. Some fishermen seem to be well aware of this last circumstance, and cut the gills with a knife as soon as the

fish is taken. A copious bleeding takes place; and they find that a fish so killed will keep much longer in a fresh state than one on which this operation of bleeding has not been performed. There are some other circumstances connected with the respiration and circulation of fishes, of which it is necessary to take notice, in order to have a full and distinct view of the economy of those most useful and interesting animals.

The heat of all animals is found to be in exact proportion to the energy with which their system works; and the best indications which we have of this energy are, the quantity of air required in respiration, and the velocity in the pulse of the circulating blood. These do not keep time with each other exactly, because time is only one element in the amount of either, and quantity is the other element, so that we must take our estimate from these two jointly. But respiration admits of much more variation as to quantity, in the same time, than circulation does; and, therefore, there may be many changes in the rapidity of breathing, arising from temporary causes, without any effect upon the pulse. If, however, we take the general habit of any animal, we shall find that there is, upon the whole, a correspondence between the two; and that the heat is in proportion to the intensity, taken jointly. This, by the way, is the only rational view of the source of animal heat, a subject upon which so much ingenuity has been wasted, and so many theories have been proposed and abandoned. Sensible heat, notwithstanding all that may be said about it, is not a thing, it is a mere accompaniment, the measure, or at all events the indication, of a certain degree of intensity of action. Nor does it appear to signify much of what kind this action may be, whether chemical, mechanical, living, or any thing else; for we have not only every reason in argument for concluding, but we have the evidence of facts to prove, that any one of those modes of action of any kind which we can name, might be brought up to such a degree of concentration and intensity, as to produce combustion in inflammable substances, or, as we say, kindle fire. We have proofs of this in the action of the animal system, in those cases of spontaneous combustion, which are too well and too minutely authenticated for leaving any room to doubt their truth, though, for the details of these, we must refer to the article COMBUSTION (SPONTANEOUS) in this work.

But whenever we would approach the subject of animal life with any thing like knowledge, it is necessary that we should always refresh our memories on this same subject of animal heat; because there is no one subject in the whole wide field of physiology in which the ignorant are so much at a loss for the way, and the learned so deeply bemired in their own fancies.

As the temperature of the element in which fishes live is never high, and varies but little, as they have nothing to do but move about, and eat, and propagate, without any burden, even of their own weight, to bear; as they have but little blood, and that blood has a slow and limited circulation, one might naturally infer that they would have a low degree of temperature, and observation shows that it is in some cases, at least, lower than the temperature of the water in which they reside. The deposit on the great bank of Newfoundland, which affords food for such inexhaustible shoals of cod, is usually, and we think with reason, understood to be made by the warm current which comes

from the tropical seas; and yet cod, when taken there at the depth of about forty fathoms, have an average temperature of about forty-one or forty-two degrees, or nearly that at which water has the greatest density, though the water at the surface may be sixty degrees or more. We are not aware that the temperature of the water, at the depth from which the fish are taken, has been observed at the same time with that of the fish, but the surface temperature has; and when we consider that the whole, or at least the greater part, is one current, we must conclude that at forty fathoms or 240 feet, it must be considerably higher than the observed temperature of the fish. This is a process on which it would be desirable to have many observations in different seas, and on different kinds of fish; because, as we cannot follow them in their submarine abodes, and study them there, we should procure intelligence of them by every means in our power.

The changes of temperature in sea-fish, and even in those of the greater part of the lakes and rivers, must be but small, even in those places where the surface freezes over. Water begins to freeze when it is cooled after being stationary, or about 40° in the mass; and though the surface sinks to the freezing point, and ice forms, the water below does not become colder in consequence of the ice on the top. No doubt the ice thickens at the under side in long continued frosts, and the frost is sometimes of such intensity and duration as that the whole volume of an accumulation of shallow water is frozen; but as long as any portion of the water remains liquid, it must, taken in the whole, be heated rather than cooled by the ice over it. There is some portion of heat produced in the act of freezing, and ice is a bad conductor, and must increase the heat under it, so that, as it advances downwards in a continued frost, it may be said to drive the action of the heat before it. No part of the sea, or of any lake, or river of considerable depth, freezes to the bottom in any part of the world; and thus, the fishes in the sea may be what we call very comfortable, even when the ice is over them.

It has sometimes been supposed that the fishes hibernate in the depths, at those seasons and in those places, where and when the surface of the water is covered with ice. This may be true where the whole volume of the water is, in consequence of its shallowness, cooled down to 32°, and then of course the whole mass will be frozen, and the fishes along with it. But so long as any portion of the water remains liquid, there is no more reason why the fishes should become torpid in it under an icy canopy than there is for the Esquimaux becoming torpid in their snow houses, in which they pass the winter with more glee and hilarity than they do the summer in their huts and tents.

The idea of their not getting air under the ice, which is one of the usually-alleged causes of their hybernal torpor, is equally untenable. In a small pond that has no communication with other liquid water below the ice, this may be and often is the case, but wherever there is a communication through liquid water to the sea, or any other extended surface open to the air, there will be no want of air in the liquid water, even though there should be a mile of ice over it. The very cause by means of which air gets at all mingled with the water, will mingle it with all connected water, whether it happens to be the part of the connexion which is open, or that

which is covered by ice. Indeed, if we are to suppose an inland lake, with a stream flowing from it, to be covered with ice, and also the stream covered a considerable way down, then upon the common principle of the pressure of fluids, the liquid water which is under the ice of the said lake, must become a sort of reservoir for air, and contains more than the unfrozen water with which it has a liquid communication.

There is therefore, nothing, either in the altered temperature or the absence of air, which can render it necessary for the fishes in the arctic seas to become torpid in the water, though there may be physiological causes which induce this in some, or perhaps in many of the species. As will be seen on referring to the article *EEL*, the eels of even the warmest parts of our own country pass the winter in a sort of hybernating state; but the cause is absolutely physiological: they seek shelter in the sand, for the very same reason that brings them down to the brackish water in the autumn,—namely, that the heat may bring forward the germs of their progeny.

When our common pond fishes are affected by loss of air during the frost, they do not hibernate; and it would indeed be absurd to suppose that the depriving of any animal of air could be the means of causing it to pass into any kind of sleep. Suffocation, the effect of which is too painful to sleep under till the operation has proceeded so far that the sleep is the sleep of death, is what takes place in these cases; and difference of climate can, in this respect, produce no difference in the result.

That many animals become torpid through cold, and some at moderately high temperatures, is true; and though the occurrence is, in all probability more rare, it is by no means impossible that animals may be frozen and revive again after they are thawed; but this is a subject upon which many experiments have not been made, and in those which have been made the result has been failure. It is generally said, indeed, and usually believed in America, that when fishes are taken at the holes of the ice on the St. Lawrence, during the intensity of the Canadian winter, they are instantly frozen; and that, while they are in this state they are as brittle as the ice itself. Thus far is most likely true; for even in the comparatively mild parts of this country, not only the leaves and stems of plants, but the bones of animals when not frozen, of course are much more easily broken than in mild weather. But it is added that, if the frozen fishes are put into cold water they are gradually thawed and become alive again. An account of the frozen eels carried to Moscow, will be found in the article *EEL*, and gives (if true) some countenance to the Canadian tale; but the attempt has been made to freeze fish and restore them to life again, in some parts of North America—at New York we believe—where it has failed. Hunter reduced the temperature of frogs to 31° or one degree below the point of congelation; but we believe he did not in any case freeze them, and unfrozen, a lower temperature than 31° always occasioned death. Indeed there is another reason for concluding that no animal, the blood of which contains salts, especially muriate of soda, can live to be frozen and again revive, for salts, and the salt which we have named especially, separate when the liquid in which they are dissolved is frozen; and thus the probability is that freezing would decompose the blood of a red-blooded animal. The eggs of birds

cannot bear to be frozen without destroying their vitality ; but the spawn of frogs can, and probably so can that of fishes. This influence of changes of temperature, especially cold, on fishes, is a subject well worthy of investigation both in a natural history point of view and in an economical one. It has been found a great improvement in the quality of salmon in the London market, to have them packed in ice ; but if we could freeze them alive and thaw them out as we wanted them, it would be much better. The subject, however, we cannot pursue farther.

*Organs of Nutrition.* In fishes, as in all vertebrate animals, these consist of a mouth, a gullet, a stomach, or an intestinal canal. The mouth is, among fishes, the only instrument which they have for catching their food ; for though there are many curious appendages to the bodies of some of them, of which the uses are little, if at all, known, it is not probable that any of them assist in the actual capture, and none of those appendages is in its structure fitted for capturing. Some of the ground fishes, the common angler, for instance, are said to make use of the filaments with which they are furnished, for the purpose of enticing other fishes within their reach ; and the chætodon rostratus, of the fresh waters of India, is said to be a very skilful marksfish, in shooting flies by means of drops of water. We shall give the account of this in the language of Dr. Shaw ; but we do not vouch for all the circumstances, which we suspect are rather too clever for a fish. " When," says the doctor, " it observes one of these (an insect) either hovering over the water or seated on some aquatic plant, it shoots against it from its tubular snout a drop of water, with so sure an aim as generally to lay it dead, or, at least, stupified on the surface. In shooting at a sitting insect, it is commonly observed to approach within the distance of from four to six feet before it explodes the water. When kept in a state of confinement in a large vessel of water, it is said to afford high entertainment by its dexterity in this exercise ; since, if a fly or other insect be fastened to the edge of the vessel, the fish immediately perceives it, and continues to shoot at it with such admirable skill as very rarely to miss the mark."

The mouth of fishes varies much more in size and shape than that of vertebrate animals of any other class ; generally speaking, its opening is horizontal, and across the mesial plane, with its action, or opening and shutting, in the direction of that plane ; but the *flat fish* form an exception to this, as will be more particularly explained in describing them. The lips are not often well formed, but some are firm and fleshy, and completely surround the mouth, while others are covered with plates of bony matter, which fold over each other. Lips of this description often increase the dimensions of the mouth, as they are capable of extension and folding up. Both jaws are moveable, though the chief motion is in the under one, and the gape is very wide : there are few fishes in which they are both of equal length ; sometimes the upper and sometimes the under is the largest, and in not a few instances one or both of the jaws are extensible, or capable of being projected forward beyond the length which they have in a state of repose. The teeth of fishes are exceedingly varied, and situated in all imaginable parts of the mouth, and sometimes outside that opening altogether. Among the mammalia, the number of teeth in the same species, or even in the same genus, is generally con-

stant ; but it is very different among fish. The teeth are often so numerous that it is difficult to count them, especially as they occupy so many different positions. The jaws are not exclusively employed to support these organs, as in quadrupeds ; the tongue, the palate, the throat, being often furnished with them. In the saw-fish, the teeth are inserted on each side of its flattened and projecting snout. In the genus *sparus*, the front teeth resemble those of the human species. They are provided with fangs, which are contained in alveoli. In many fishes, the teeth are formed of processes of the jaw-bones covered with enamel. Those of the shark tribe adhere merely to the gums, or, at least, to a firm cartilaginous substance which covers the jaw. They are not formed, as in the mammalia, by the addition of new layers, one within the other, but apparently in a manner resembling the formation of bone. They are at first soft and cartilaginous, and pass, by successive gradations, into a state of hardness and density not inferior to that of ivory. In the skate, the teeth consist of an assemblage of tubes, covered externally by enamel, and connected to the jaw by a softer substance, which probably sends processes or vessels into those bony tubes. The teeth of fishes are in general bent inwards, to enable them to retain their prey. As few fishes masticate, they have seldom any teeth which resemble grinders, although those which live on the harder shell-fish have teeth fitted for triturating them. In the classification of fishes, the teeth furnish several important characters, which are little liable to variation. In the shark tribe, in particular, the teeth exhibit many remarkable differences in form, sufficient, in the absence of other characters, for the discrimination of the species. The form of the teeth and their arrangements are not less various than the places on which they are situated. Generally speaking, they are individually in the form of cones, or they are hooked. If these are placed in several rows, they are sometimes called *carded teeth*, because they bear a resemblance to the teeth of the instruments used in carding wool and other matters ; if they are very small, numerous, and thickly set, they are called *velvety* (*en velours*) ; and if long and close they are called *brushes*. Sometimes, however, the individual teeth are too minute for being seen, though they may be felt as a sort of granular roughness upon the surface. In this case they are said to be *asperities*. Though the teeth of those species which feed upon *fuci*, and other vegetable products of the sea, are adapted for biting off or dividing those products, and some of the teeth of the sharks are capable of dividing and tearing in a dreadful manner, yet there is no provision in the mouth of a fish by means of which mastication or chewing can be performed. Indeed this is an operation exclusively confined to the mammalia, which accordingly are the only animals which have a grinding or a lateral motion in the jaws ; and thus all fishes are obliged to swallow their food in the same manner in which it is at first taken into the mouth. The lips, in the bony fishes especially, have no muscles by means of which they can be closed and compressed so as to assist in the act of swallowing, though they have often masses of considerable size to swallow. Instead of this they have a peculiar apparatus, to which we made some allusion when speaking of the progress of the water in breathing. Behind the front teeth, or those in the anterior part of the jaw and the vomer, there is a reduplication of

the internal lining of the mouth, which forms a sort of valve; and this valve also assists in conducting the food towards the gullet, which is also promoted by the teeth on the tongue and palate, which being reflected or bent towards the opening of the gullet, prevent any return. When it arrives at the pharynx, or posterior part of the mouth, it, in most of the species, meets with a third set of teeth on the pharyngeal bones, by means of which it is conveyed into the gullet. This canal is of very ample dimensions, not much less than the whole capacity of the mouth; so that many fishes appear internally like a sack as far down as the stomach. The gullet is abundantly furnished with muscles, the action of which furthers the progress of the food downwards; and it is possible that in many instances the process of digestion, or decomposition of the food, begins here, as it is known to do in many of the reptiles. The stomach of fishes is in general thin and membranous, differing little in its structure and appearance from the gullet. It frequently contains the remains of crustaceous animals, still retaining their form, but greatly altered in consistency. Hence naturalists have concluded, that the food is reduced by solution, and not by trituration. But in some fishes, particularly those which subsist principally on shell-fish, the stomach has thick muscular coats. Its shape is considerably different in the different species, but the characters furnished by this organ are seldom regarded. The intestinal canal varies much in the different species. In some it is straight, in others it has convolutions, but it is never so long as in most of the mammalia. In many bony fishes there are a sort of cæcal appendages to the canal; but it is in the cartilaginous fishes only; which, though by far the least perfect in the ossification of their skeletons, are the most so in the other parts of their economy. The abdominal viscera are enclosed in a membranous peritoneum, which has small openings near the vent, by which any liquid in the cavity of the body can be discharged, but none can readily be admitted. The greater number of fishes are, strictly speaking, *monostomata*, or have only one vent or opening for all sorts of discharges.

One remarkable viscus in fishes, to which there is nothing correspondent in any other of the vertebrated animals, is the air-sac, or air-bladder, which some have and some are without, and the real use of which in the economy of the animals is not known. Some notice of this curious viscus will be found in the article AIR-BAG; but we shall not enlarge upon it, as all that is known is that it cannot have the use which is commonly supposed—that of regulating the specific gravity of the fish. If this bag were to be alternately filled and emptied of air, according to the different pressures of water to which the fish was subjected at different depths, then, we must suppose that the fish must have the means of filling it. A “gas-work” in the cavity of a fish for this purpose, is not likely, and besides there is no apparatus. Neither is the air with which this muscle is filled, the refuse of that from which the oxygen apart necessary for the purposes of life, is taken in the process of respiration; for though the greater part of the contents is nitrogen, the quantity of oxygen in it increases as the fish to which it belongs is an inhabitant of deeper water. As little can it be filled from the external air when the fish is at the surface, because its contents are not the same as the atmosphere; and

also if supplies were taken in there it would hinder the descent of the fish. Besides, of fishes that have similar habits, some of them surface fishes, and others bottom or ground ones, some have this viscus, and others are without it. Thus, the only conclusion to which we can come in the present state of our knowledge is, that we are in utter ignorance as to its real use. The air-bag of fishes, when cleared of fatty matter, is perhaps the purest gelatine which is obtained from the whole animal kingdom; and as such, it is of much value both as an article of food and in the arts.

Though we do not think it necessary, in this brief outline, to give any account of those secretions of the liver, the pancreas, and other viscera of fishes, which assist in the assimilation of their food, and in other parts of their economy, and which do not appear to differ very essentially from the same precedents in other vertebrated animals; yet there is one peculiar secretion of the surface which is so peculiar, that we cannot wholly pass it over in silence. This is the secretion with which they are covered over, and which appears to be the means by which their bodies are preserved from injurious maceration by the water in which they float, and by means of which also, they are allowed to range thereon in whatever direction may be necessary.

The last of these is a matter of more consequence than they who have not been in the habit of attending to such subject would readily suppose. According to a well-known law of bodies floating in water, if that water were to wet them completely, they would have a constant tendency to come on shore; and though, in the case of a fish, this might be occasioned by perhaps not a very great deal of muscular effort, yet that effort would be a continual one, and would wear them out more than a greater effort made only at intervals. The friction of the water in the case of a wet fish, would also be a considerable disadvantage, but the grand disadvantage, however, would be the decomposition of the epidermis, and the consequent pain and destruction of the whole animal. All these bad effects are prevented by the mucous secretion.

As might be expected from their difference in other respects, the production of this mucus is not quite the same in the bony and the cartilaginous fishes. The following account of it in the skate, by the late Dr. Monro, will show how intimately it is connected with even the most important part of the system. “First,” says Dr. Monro, “I have discovered one very elegant serpentine canal between the skin and muscles, at the sides of the fine apertures into the gills. Further forwards it surrounds the nostrils; then it passes from the under to the upper part of the upper jaw, where it runs backwards as far as the eyes. From the principal part of this duct, in the under side or belly of the fish, there are not above six or eight outlets; but from the upper part near the eyes, there are upwards of thirty small ducts sent off, which open upon the surface of the skin. The liquor discharged from these has nearly the same degree of viscosity as the synovia in man. But, besides the very serpentine duct I have been describing, I have remarked on each side of the fish, a little further forwards than the fine breathing holes, a central part from which a prodigious number of ducts issues, to terminate on almost the whole surface of the skin, excepting only on the snout or upper jaw. At these

centres all the ducts are shut, and in their course they have no communication with each other. In these two central parts, or on the beginning of the mucous ducts, a pair of nerves nearly as large as the optic, terminates, and which is a curious circumstance with respect to them, they are white and opaque in their course, between the brain and their ducts, but when they divide, they become suddenly so pellucid that it is impossible to trace them further, or to distinguish them from the coats of the ducts."

In the bony fishes, the distribution of this mucous secretion is somewhat different. The orifices from which it is discharged are principally either on the forehead, or along the lateral line. This line by the way is a peculiar marking in fish. In some it is not found, as in the lamprey; in most fishes it is single; but in some, as in the launce (*ammodytes*), it is double; and there are some fishes, indeed the greater number, which have it straight; but in others it makes a singular bend upward, opposite to the cavity of the body. This line is differently coloured from every other part of the side of the fish; and its colour fades sooner after death than the colour of any other part. This, together with the accumulation of the mucous ducts upon it, shows that it must have some important connection with the living action of the fish; though what this connection is has not been ascertained. The mucus itself has not been analysed with sufficient care, but it seems to be something in the nature of albumen, probably in nearly the same state as it exists in the epidermis, though it is liquid in the one case, and solid in the other. It is indeed a substance which, though plentiful, is not very easily examined, at least in such a manner as to judge of it while the fish is living and under the water, because it seems so intimately connected with the nervous system of the fish, that there is no knowing how great a change may be produced in it by death, or even by exposure to the atmosphere.

*Organs of sensation.*—The senses of fishes, like those of all other animals, form a very important part of their history; and we know from various facts, that in many fishes, not only particular senses, but sensation generally must be very acute, from the readiness with which they are affected by slight changes of the weather. In a trouting stream for instance, when the sun is under a cloud, and that cloud brings, as it very often does, a slight curl upon the water, the trout will rise to the fly with the greatest readiness; and also be seen sporting about in all directions near the surface; but as soon as the cloud passes, and the ripple along with it, not a trout will rise to the most skilful angler; and one may observe them lying perfectly still near the bottom of the shallows. Under those circumstances there can be little difference of temperature in the water, for the two may succeed each other several times in the course of a few hours, and therefore the trout must be in some way sensible to the influence of light. The same species of fish, and many others, are also remarkable for the acuteness of their vision. Every angler in clear streams knows how vain it is to tempt a trout, if either his shadow or his reflection is thrown upon the water; and even if the angler is on the right side, the passage of a countryman along the opposite bank, or a cow coming to drink, may spoil his sport for the day. Of the hearing of fishes we know less; but we do know that water is a conductor of sound in a pecu-

liar way, though, as we cannot make our experiments on a direct parallel, our own ears being of a different structure from those of fishes, we can arrive at no very conclusive result on the subject. As to the sense of smelling, though some have gone so far as to say that a trout knows a living worm from a dead one by the smell, yet as the same sense does not enable the very same trout to distinguish an artificial fly with a hook in it, from a real fly upon the water, we must conclude that this sense is exceedingly imperfect. Of taste fishes can have but little, and indeed no animals but such as masticate their food, or at all events have soft tongues, have this sense in any high degree. But fishes, at least with very few exceptions, swallow indiscriminately almost any substance which is floating; and sailors sometimes amuse themselves with "giving a shark his grog," as they term it, that is throwing a corked empty bottle overboard, in order that a shark may swallow it.

The brain in fishes, if we are to suppose that the acuteness of sensation bears any proportion to the development of that organ, is very small and very soft. In the tunny it is less than one seventeen thousandth part of the body; and in carp, which have it in a greater proportion than most of the species that have been examined, it is less than the five-hundredth part. The peculiar manner in which the brain of the whole finny race is developed, or rather the portions of it which have the greatest development, would lead us to conclude that, if we are to connect the faculties and propensities of the animal with this organ, the chief propensities of fishes are those that relate to mere feeding and motion.

Of the peculiar organs of sense, the eye is the most conspicuous, and in all probability the most useful to the animal. As is the case with all vertebrated animals, fishes have only two eyes, placed, generally speaking, in opposite sides of the mesial plane. The flat fish no doubt form an apparent exception to this; for in the usual way of regarding the darker coloured side as the back, and the lighter coloured one as the belly, the eyes are always on the upper or back part, and towards one side of the mouth, sometimes the left side, and in other species the right, as will be mentioned in the article FLAT-FISH. But this apparent deviation from the typical, and indeed the invariable position of the eyes in vertebrated animals, is not real in the fishes under notice. There is a twist in the neck, or at all events in the upper portion of the spinal column, which turns the mesial plane in an oblique direction; so that when it passes from fin to fin in the body of a flounder, it passes through the head in a curve, from a point between the eyes through the mouth to the middle of the lower jaw. In their size the eyes of fishes vary considerably; and though the general law be that the eye is large in proportion as the fish inhabits the deeper water, yet there are some exceptions. Thus in some species of eel the eyes are so very minute, that they are barely visible, even in a tolerably large specimen. But the exception here is also more apparent than real; for though those eels do inhabit the bottom of those waters in which they are found, yet they are never found at any great depth. Besides, eels live partly in the water, and partly in the mud, being as it were a sort of water moles; and therefore like the moles which burrow in the ground, and almost all animals which enter partly or wholly into the soil, they have less need of large eyes, and such eyes would be much more liable

to injuries. We may therefore consider it as a general law that where fishes inhabit the water, and do not bury themselves at least over the eyes in the ooze at the bottom, the size of the eye is in proportion to the depth. Thirty or forty fathoms may perhaps be considered as the average depth of a cod fish on the ground banks; and the eye of a fish of this description is at least as large as that of an ox. Thus the size of the eye guides us to the position which the fish holds in the water; and in like manner the situation of the eyes points out in what direction the fish looks out for its food. Those which lie at the bottom, or swim near the bottom, and look for prey over them, have the eyes in the upper part of the head, and often very near to each other; and in order to answer this habit, the mouth of such fishes very generally opens upwards also,—that is to say, the lower jaw projects beyond the upper one, and rises up in front of it. On the other hand, if the fish has to seek its food below it, the eyes are placed wide apart, and fishes of this kind very frequently have the muzzle or frontal line from the eyes sloping downwards as if truncated, and the opening of the mouth below. Fishes which follow their prey in level chase, have the eyes placed more nearly in the situation of those of land animals of the chase; and in them, whatever may be the nature of the prey, the opening of the mouth is pretty nearly straight.

This connection between the form and position of the eyes, and the mouth of fishes, and also with the depths at which they feed, and the direction in which their food is situated with regard to them, is very important in the natural history of fishes, and affords perhaps a surer guide to the character of any “strange fish” that we meet with, than half the characters which are given, or which can be given in the systems. Indeed, systematic ichthyology is very imperfect in this respect; for even where the characters of the genus, the species, or even the larger division, are given with the greatest accuracy, they do not of themselves give the slightest indication of the part of the sea in which we are to seek for that species of fish with the greatest certainty of success; and it would certainly be desirable to combine something of this kind with the systematic view, though to carry it into details would most likely be a work of immense labour and much uncertainty. It would also be a good plan, if the execution of it were possible, to connect the qualities of the fish as food, with the characters indicating the depths at which they are found; but this is a point to which we shall have occasion to recur.

The eyes of fishes are placed in *fossæ* or sockets in the bones of the head, much in the same way as those of the other vertebrated animals; but they are in general destitute of eye-lids, neither have they any projecting arch in the form of an eyebrow, or any of that apparatus which in the land vertebrata is employed in lubricating and cleaning the eyes. Whether fishes know sorrow we cannot tell; but we are sure that they cannot “weep over their woes,” for they have no tears. In the moon fish (*Tetodon mola*) however, the eye is in great part covered by a circular lid, which has merely a perforation in the middle for admitting the light. In the greater number the skin passes over the eye without any division, so that that organ is as well defended as any other part of the body, only the skin over it is transparent. In removing the skin from a common eel, there is no perforation answering to the eyes. The whole skin appears of

equal strength, only there are two little patches corresponding to the eyes, which are transparent and colourless.

But in some fishes there is not this transparent spot, or window for the accommodation of the eye. In some the texture, and even the colour, of the rest of the skin extends to the part which covers this organ. In the trunk fishes (*Ostracions*) there are the same striæ or rugosities in the skin over the eyes, as in that of the surrounding parts; and in that singular inhabitant of the northern seas (*Gastrobranchus cæcus*, *Myxine glutinosa* of Linnæus,) the common integuments which pass over the eyes are so exactly of the same colour and texture as the rest, that the animal appears to have no eyes at all until the skin is removed.

The element in which fishes live, by the constant motion of the water, renders the use of eyelids and lubricating fluids perfectly unnecessary; and their exposure to the same fluid under a heavy pressure, owing to the great depth, requires a far more firm covering than the common coat which encloses the aqueous humour of an eye which is used only in the air. A projecting eye, or one convex outwards, would be equally inconvenient, and thus the surface of the eyes in fishes is flat; but this is compensated by the greater magnifying power of the crystalline lens. The flat cornea of the eye in fishes, besides being that which sustains least injury from the passage of the fish through the water, and from the chance of striking against obstacles, has some advantages in the greater quantity of light which it sends to the sentient part of the eyes, than would be sent by a convex surface. It is only at the middle of such a surface that the whole of the light falling upon it enters; for everywhere else a portion is reflected off, corresponding to the angle at which the circular surface turns away from a plane at right angles to the axis of its centre; and by this means, great part of the light which falls upon the external surface of a very round or protuberant eye, is dispersed through the surrounding atmosphere, and would be lost for all useful purposes in vision. But when the surface of the eye is flat, as it is in fishes, there is no more light reflected away from one part of it than from another; and therefore, of such quantity of light as may reach the eyes of fishes in the depths of the sea, there is much less lost than there is of that which falls upon the convex eyes of land animals. No doubt there is a much more scanty supply of light under the water, especially at considerable depths, than there is upon the land; but it is this which, more than any thing else, shows the beautiful adaptation of the eye to the circumstances under which it is used; and no one who reflects on the subject will fail to perceive that in the coincidence of this with all the other advantages which the fish derives from the peculiar structure of this organ, there is evidence of wisdom far surpassing not only the wisdom of man, but the estimation of the human mind, in any other feeling than that of simple adoration.

In fishes the general form of the entire eye with its coats, its lenses, and its humours is nearly that of a hemisphere, of which the flat side is external, and the interior one spherical. In the skate, the superior part is also flattened, so that the vertical diameter is to the transverse as one to two. This flatness of the anterior part of the eye is compensated by the spherical form of the crystalline lens. This body is

more dense in fishes than in land animals. Monro found the crystalline lens of an ox to be 1104, while that of a cod was 1165, water being reckoned at 1000. The crystalline lens projects through the pupil, and leaves scarce any space for the aqueous humour. The vitreous humour is proportionally small. The portion of the axis occupied by each of the three humours of the eye, in the herring for instance, may be expressed in fractions as follows: aqueous humour  $\frac{1}{3}$ , crystalline lens  $\frac{2}{3}$ , and the vitreous humour  $\frac{1}{3}$ . The spherical form of the crystalline lens has been already alluded to; but the following table, from the observations of Petit and Cuvier, will exhibit more clearly the proportion between the axis and the diameter in a few species.

The axis to the diameter in the—

Salmon as . . . 9 to 10	Whiting . . . 14 to 15
Sword-fish . . . 25 26	Shark . . . 21 22
Shad . . . 10 11	Ray . . . 21 22
Pike . . . 14 15	Herring . . . 10 11
Barbel . . . 11 12	Tench . . . 7 8
Carp . . . 14 15	Eel . . . 11 12
Mackerel . . . 12 13	Conger . . . 9 10

In the eyes of fishes the sclerotic coat is firmer than it is either in mammalia or in birds. It is here cartilaginous, semi-transparent, and elastic, and sufficiently solid to preserve its form of itself. In the salmon it is of the thickness of a line posteriorly, and of an almost bony hardness before. This is frequently the case in other fishes, especially near its junction with the cornea, where it sometimes appears like an osseous ring. The outer layer of the choroid coat is either white, silvery, or gold-coloured, and is very thin and a little vascular. The inner coat, to which the term *membrana ruyschiana* has been applied, is in general black, and covered every where by mucous substance. In the ray, however, it is transparent. Between these two membranes of the choroid coat there is a body of a brilliant red colour. Its form is usually that of a cylinder, formed like a ring round the optic nerve; the ring, however, is not complete, a segment of a certain length being always wanting. Sometimes, as in the *Perca labrax*, it consists of two pieces, one on each side the optic nerve. It is considered by some as muscular, and enabling the eye to accommodate the figure to the distance of the objects; while others regard it as glandular, and destined to secrete some of the humours of the eye. This gland, we may add, does not exist in the *Chondropterygii*, as for instance in the rays and sharks. In the eyes of fishes the iris has generally a rich metallic lustre, usually of a golden or silvery tint. This is occasioned by its transparency, which allows the natural colour of the choroid or painted coat to be seen through it. In different species the pupil or opening of the iris differs in shape; but, generally speaking, it is either a circle or an oval. In the salmon, and in some other genera, however, it is drawn out into a sharp angle at the fore part; but what may be the use or effect upon fishes of those differences in the form of the pupil, we have no means of ascertaining, inasmuch as we cannot refer them to certain habits of the animals, as we can in the case of those mammalia which have the pupil contracting in an oval form upon an axis either vertical or horizontal. There is one species of fish, *Anableps tetraphthalmus*, which has a very peculiar formation of the eyes. This fish has in reality only two eyes, but there is a double pupil to each, which gives it the appearance of having four. See the article *ANABLEPS*.

In the skate the upper edge of the pupil is formed into several stripes arranged like radii of a circle, of a golden colour on their external surface, but black on the internal one. In ordinary states of the eye they are folded back and concealed between the upper margin of the pupil and the vitreous humour; but if pressure is applied to the upper part of the eye, they unfold and come partially over the pupil like the blind of a window. In the torpedo or cramp fish there is a veil of this kind which is capable of entirely covering the eye. Of the bony fishes, and indeed of most of the cartilaginous ones, none possess an apparatus of this kind, though in most fishes there is a vertical veil at the corner of the orbit which covers a small portion of the eye. The eyes of fishes are, generally speaking, supported on a mass of elastic jelly-like matter, which acts as a spring, and prevents them from receiving any concussion even in the most violent motions of the fishes. But in the cartilaginous fishes the support of the eye is quite different from this. In them the eye is placed on one end of an elastic peduncle or stalk of cartilaginous substance, which has its other extremity inserted in the bottom of the orbit, and the muscles, by acting on the eye placed on this flexible peduncle, can give it extensive motion in every direction, while, when the muscles cease to act, the elasticity of the peduncle brings the eye back to the mean position. Fishes which have eyes of this description are generally very voracious in their dispositions, and this mobility of the eye gives them great command of all the space around them.

We have occupied so much space in describing the eyes of fishes, that we can spare but little to their other organs of sense; but, in respect of them less is necessary,—first, because they are much less perfect, and the fish appear to depend less upon them for information and guidance; and, secondly, because we do not know how ears and olfactory apparatus may act under the surface of water. Sound, as we hear it, is heard by peculiar pulsations of the air; and scent, we have reason to believe, is occasioned by particles of the odorous body which diffuse themselves through the air, and though we often experience scents emitted by the air to the water, we know not what may be the effect of similar successions under the surface. When an odorous substance is floating in a running stream, we have no reason to suppose that any particles capable of affecting organs of smell can be given out by it against the current; and if we may reason from analogy, in a case where we can reason from nothing else, we must be led to conclude that such emanations can make their way through the water only to very short distances, so that in an ample body of water it does not appear that there can be much scent.

Then, in the great body of the oceanic waters which is the grand habitat of the fish—a field which man has not either to plough or to sow, but from which he may nevertheless reap, and does reap when even moderately industrious, a most abundant harvest—there are other causes capable of destroying all odorous matter. The sea contains a vast quantity of chlorides, or at all events of hydrochlorides, substances most destructive of the effluvia, especially the noxious effluvia, of bodies in the air, and thus we may consider the sea as the grand laver of purification for the globe, and this fact is against the existence of much sense of smell in fishes.

In the case of sight, the state of things is very different, and fishes may, especially from the microscopic form of the crystalline lenses of their eyes, have as perfect vision at depths to which we suppose only a small portion of the light of the sun ever reaches, as we have in the noontide beams of the luminary. We must not judge of the capacity of any eye for seeing under water, from the difficulty that one has of seeing into it; because, without any reference to the clear or muddy state of the water itself, the quantity of light which the surface reflects when the rays fall obliquely upon it, is greater than that which is not out of the water. Of this we have a case nearly parallel, when we stand in a very oblique position with regard to a window, and endeavour to see what is going on inside. The glass of the window may be nearly as transparent as the air itself, and it may be perfectly flat, so as not to break the reflected light; but the more transparent, and the more flat and smooth, the more completely does it obstruct our vision by the reflected light, if our position has the requisite degree of obliquity. But notwithstanding our inability to see through the window into the apartment under these circumstances, the people in the apartment may be enjoying even a quantity of light which is painful to them, and they may be capable of discovering the most minute object, not only inside the room but through the window.

The situation of fishes in the sea is much the same as that of the inmates of the room in this illustration, and we, the observers of the fishes, are like the spectators out of doors, incapable of seeing what goes on, either if our position is oblique, or if the light falls obliquely on the surface. And we have the evidence of direct observation in proof of this. There is no reason why the water of the sea should be more transparent in the regions of the equator than in those of the poles; and yet, from the mere fact of the solar light falling nearly perpendicular upon the surface of the water in those seas, they are as clear as crystal, and one can see the whole of the operations that are going on even though the depth be forty fathoms or more. In our latitudes we can see but a very small depth into the sea, and therefore the operations which go on under the surface are a sealed book to us. But it is only we who are thus left in the dark, for there is abundant light for every eye which is under the water. Those who have so practised diving that they can do it with the eyes open, are able to see the smallest object at the greatest depths which they can reach; and there is no doubt that, from the peculiar structure of the eye in fishes, and the increase of the field of view in proportion to the depth, they can see the most minute objects at the greatest depths which they inhabit, and that, at all depths, sight is the sense on which they chiefly depend. Still fishes have organs both of smell and of hearing, and without a slight notice of these our sketch of them would be incomplete.

The organs of smell vary more than in the mammalia or birds. In many, the nostrils have only the opening on each side; but in others, this is parted by a septum which gives them the appearance of having four nostrils. Sometimes the openings are round, sometimes oval, and sometimes they are longitudinal slits. They are either on the mouth or between the eyes, or in an intermediate position; and they have occasionally the form of short projecting tubes. They are furnished with a few muscular fibres, and so must

be capable of some motion; but to what extent, and for what purpose, it is by no means easy to determine.

On examining the inside of the nostril, we find in sharks and rays a large lamina, which extends the whole length of the opening, with smaller parallel laminae branching off from it on each side like the teeth of a crab; while in most fishes of both divisions these laminae are like rays with a tubercle in the centre. In the membrane which lines the nostrils of the pike, the vessels are black; but in most fishes they are red; and there are between the nasal vessels in all fishes, papillae which discharge a thick mucus. The olfactory nerves, at their origin, form swellings or knots, so large as frequently to have been mistaken for the real brain. These tubercles in skates and sharks are united into one homogeneous medullary mass, from each of the lateral parts of which the olfactory nerves arise. In the flounder, the herring, pike, perch, and salmon, there are two pair of tubercles, the anterior of which is smaller than the other. In the cartilaginous fishes, as the skates and shark, the olfactory nerve is very soft. It is, in them, a bulb which passes obliquely forward towards the nares, which are at a greater or less distance from the brain, according to the species. The spinous fishes have the olfactory nerve very long and slender. In those which have the snout elongated, this nerve is received into a cartilaginous tube. In those with short snouts, the nerve is surrounded by a fine membrane only, which appears to be the same as that which contains the fat or oily humour that covers the brain. In the haddock, and some other fishes, the olfactory nerve, in its course from the brain to the nose, passes through a cineritious ball, which resembles the cineritious matter connected in our body to the olfactory nerve within the cranium. When the olfactory nerve arrives behind the folded membrane which we have described, it is dilated to be applied to the whole of its internal and convex surface. In some fishes no previous enlargement takes place; while in others the nerve swells into a real ganglion. When expanded, it has been compared to the retina, but the filaments of which it is composed are more distinct.

As a specimen of the opinions which are held by those who speak and write with not the most profound reflection, but which sort of opinions are unfortunately the most prevalent both in conversation and in books, we shall quote a short passage from Dr. Shaw's General Zoology, which, however, the reader, who bears in mind the readiness with which artificial flies and wooden minnows are taken, will perceive, carries its own refutation. "If," says Dr. Shaw, "you throw a fresh worm into the water, a fish shall distinguish it at a considerable distance; and that this is not done by the eye is plain from observing, that after the same worm has been a considerable time in the water, and lost its smell, no fishes will come near it; but if you take out the bait, and make several incisions into it, so as to let out more of the odoriferous effluvia, it shall have the same effect as formerly. Now it is certain, that had the animals discovered this bait with their eyes, they would have come equally to it in both cases. In consequence of this smell being the principal means they have of discovering their food, we may frequently observe them allowing themselves to be carried down with the stream, that they may ascend again leisurely against the current of water; thus the odoriferous particles swimming in that

medium, being applied more forcibly to their organs of smell, produce a stronger sensation."

But though we have very little ground for supposing that there is any application of the olfactory nerves of fish which bears much analogy to the sense of smell in animals which live in the air, yet this apparatus is so elaborate, and so constant to its form in the different genera and even species, that it would be very desirable to know more about its use. Not only on account of the light which it would throw upon the physiology of fishes, but because the difference in this apparatus might be made good and permanent systematic characters. That this apparatus is of very little use, either in directing fishes where to find their food, or how to select it, is highly probable; and, therefore, in the present state of our knowledge, or rather, we should say, perhaps, of our ignorance, the most rational conclusion is, that those nostrils, which, from their structure and the nature of their internal coating, must be very sensitive in some way or other, teach the fish to avoid water mixed with substances which would be deleterious to its health. In man, and in all those animals which have soft tongues and breathe through the nostrils, there is a very close connection between the senses of smell and taste, especially when the taste is that of an aroma, which affects the palate rather than the tongue, as is proved by the fact, that if a substance having this aroma is taken into the mouth, and the nostrils held closed, it is not only impossible to tell what aroma it is, but there is little or no perception of aroma at all.

Though the vulgar opinion often is, that fishes do not hear, the contrary is established by many facts. Pond fishes, such as trout and carp, have been trained to come regularly and be fed at the ringing of a dinner bell, while others have answered to a whistle. It is reported that the Romans, among whom pet fishes were very common in the days of their greatest luxury, could call any one fish by name, and the fish would answer. Perhaps this is going a little too far; but from the observations which have been made in modern times, it is certain that fishes not only hear, but hear very readily; and there are some other circumstances which would lead one to conclude that they are susceptible of a good deal of education, and capable of showing considerable attachment. In showery weather, river fishes will often be seen feeding and moving about with the greatest activity, and biting as freely as the most devoted angler could desire; but if there comes a loud peal of thunder, down goes every fish to the bottom, and the sport is over for some time. So also the discharge of artillery, or muskets, or shouting scares the fish; and, therefore, fishermen are usually silent when shooting their nets.

In the bony fishes, and also in the cartilaginous ones, which have the gills free, there are no external openings of the ears; but in those fishes which have fixed gills, there are in the occiput two small openings, sufficient to admit the head of a pin, which lead to the internal ears. In fishes having the gills free, the internal organs of hearing are situated in the sides of the cavity of the cranium, and fixed there by a cellular tissue, consisting of vessels and bony or cartilaginous bristles. In fishes with the gills fixed, those organs are enclosed in a particular cavity formed in the substance of the head. This cavity is situated on the side and posterior part of that which contains the brain, with which it does not communi-

cate, except by the holes that afford passages for the nerves. The sac exhibits many differences as to size and form in the different species. Besides the ordinary viscid fluid, there are some small cretaceous or chalky bodies suspended by a fine nervous tissue. In the osseous fishes these are three in number, and are white and hard, like porcelain. In the cartilaginous fishes with the gills free, these bodies are less numerous, and their consistency is seldom greater than that of moistened starch. The use of this peculiar part of the auditory organs is not very well known; but it is supposed that they communicate to the nerves the vibrations of the water. As the ears of fishes are much more simple in their whole structure, than those of land animals, and as the parts of which they are composed are not easily examined with sufficient accuracy, they cannot well be made grounds of systematic arrangement.

*Reproduction of Fishes*.—This, though one of the most general and energetic of all natural operations, is involved in very considerable obscurity; and human art has not been applied to the increase of the numbers or the improvement of breeds; and, indeed, from the rapidity with which all fishes multiply, this does not appear to be absolutely necessary. Fishes are, generally speaking, either oviparous, or producers of eggs which are brought to maturity external of the body of the mother, or they are ovoviviparous, that is producing the eggs in one part of the body, and bringing them to maturity in another, discharging the young alive. In most fishes the two sexes are distinct, and in different individuals; but in some few instances, it is alleged that they are true hermaphrodites, or have both sexual energies in the same individuals. This is, however, an obscure part of the subject, liable to many uncertainties; and, therefore, we shall not enter into any of its details. Leaving them out of the question, we have the two divisions of oviparous and ovoviviparous, or, as they may be more popularly termed, fishes which are hatched externally of the mother, and fishes which are hatched internally.

Of the first, which is by far the most numerous division, and also the most prolific, the whole have free gills, though some of them are bony, and others cartilaginous in the skeleton. The female organs, which are popularly designated roes, are generally double, but sometimes single; and the corresponding organs of the males, which are properly called milts or whites, are of pretty similar form, though of very different consistency. The roe consists of a vast mass of eggs contained in an apparently very thin membrane, which are at first small, but gradually increase, and are large and very distinct at the time when they are excluded from the body. The milt contains a thickish fluid, which merely increases in quantity, so as to arrive at its greatest bulk when the ova or eggs of the female are in a condition for being deposited.

It is for the purpose of bringing this substance to maturity, that so many fishes seek the warmer parts of the waters at certain seasons of the year; and it is for the purpose of depositing their spawn, that the greater number of our shoaling fishes, which are at other times in the deep water, or discursive through the seas, come upon the coasts. The places to which various species of fishes resort for these purposes, the mode in which the eggs and milts, or spawn as the two jointly are called, are deposited, and the substances to which they are attached for the purposes of stability or protection, are, however, so numerous, that it is impos-

sible to generalise them. In general the approach toward the shore of fishes for the purpose of spawning, is an operation of the greatest possible value to man. At the time when the roes and milts are coming to maturity, all the energies of the fish appear to be excited to a more than ordinary degree; so that at this time, and up almost to the period when the spawn is ripe for being deposited, the fish are in the best condition for the table; and thus they may be said to come on the shores almost on purpose to be caught. The eggs of different fishes vary much in colour; but those of all the species in the present division, agree in being perfectly globular. None of them have shells, but they are enveloped in a membranous integument. This integument is more or less firm according to the species. The yolk, instead of occupying the centre, as in the eggs of birds, is placed laterally, and is surrounded by the glaire or albuminous matter. Between the yolk and the glaire is situated the germ or embryo. The germ becomes ready for exclusion at very different periods, according to the species. Thus the egg of the carp is said to be perfected in the course of three weeks, while that of the salmon requires as many months. But in the eggs of the same species, a great deal depends on the temperature to which they are exposed. In the same pond, those eggs are soonest hatched which have been deposited in the shallowest water. As the embryo is developed, the heart first appears, afterwards the spine, eyes, and tail. The organs of motion are evolved in the following order. The pectoral fins first make their appearance, and afterwards those of the tail; the dorsal fins follow, and then the ventral and anal fins. In fishes, such as the salmon, which bury their spawn under the gravel of rivers and brooks, the appearance of the young at first is very singular, as they come up through the covering, while the lower part of the body remains attached to the remainder of the egg below.

In fishes which hatch their young, the eggs are fecundated internally; but observations have been made on comparatively few fishes of this division, and therefore our information respecting them is comparatively vague. The sharks and rays are the ones to which most attention has been paid; and the following remarks will show in outline the progress of the young in these. The females have two ovaries, or egg vessels, situated at the sides of the spine, and containing eggs in different stages of forwardness. An oviduct proceeds from each of these, the anterior extremities of which are united to the diaphragm and spine. Internally, these ducts are covered with glandular papillæ, and pass through a large glandular body. After passing this body, they dilate into a large sac. When the ova pass into the oviduct they are carried to this glandular body, which is supposed to secrete the glaire or albuminous part, and afterwards conveyed to the uterus, where they receive the shell. At what period the egg becomes impregnated, or in what manner the operation is performed, are questions to which no satisfactory answers can be returned. The eggs are of a quadrangular form, with processes at the four corners; they are called sea mice by some, but by fishermen they are called skate-purse, or shark-purse. The shell has a horny consistence, and may often be observed, at certain seasons, among the rejectamenta which the sea casts, as being no longer useful in its economy. When the young fish have been perfected in the uterus, where they derive

their nourishment exclusively from the egg, and not from the mother, they are ejected through the openings of each uterus, at the sides of the cloaca, and upon escaping from the shell, enjoy immediately an independent existence, and begin to search after new nourishment.

The individual broods, or shoals of production, in fishes of this description, are not nearly so numerous as those of the oviparous fishes, though from the different stages of growth, at which the eggs are contemporaneously found in the females, it is probable that the period of production lasts considerably longer. Such fishes have not the same necessity for migrating in search of proper breeding grounds as the others, and therefore the whole sea is comparatively free to them at all times in proportion to their habits. It farther appears that they are not so much exhausted by the labour of reproduction, and thus their flesh does not get so much out of season as that of the others. This may also, in conjunction with the softness of the bones, which never know old age (see *CHONDROPTERYGII*), contribute to the large size, inexhaustible strength, and long life of these fishes.

In the sea, it does not appear that there are any hybrids among fishes, any more than there are among land animals in a state of wild nature; but the case is said to be different in ponds, in which carp and trout are sometimes said to blend their several qualities. This point, though one of some interest if fish were cultivated as they ought to be, is one which is involved in very considerable obscurity.

The following table, the result of useful observations which are extracted from the Philosophical Transactions for 1767, will give some idea of the relative fertility of several species of oviparous fishes:—

Fish.	Weight. oz. dr.	Wgt. roe. gr.	No. of eggs.	Date.
Carp .	25 5	2,571	263,109	.. April 4.
Codfish .	0 0	12,540	3,686,760	.. Dec. 28.
Flounder .	24 4	2,200	1,357,400	.. March 14.
Herring .	5 10	480	36,960	.. Oct. 25.
Mackerel .	18 0	1,223	546,681	.. June 18.
Perch .	8 9	765	28,323	.. April 5.
Pike .	56 4	5,100	49,304	.. — 25.
Roach .	10 6½	361	81,586	.. May 2.
Smelt .	2 0	149	38,278	.. March 21.
Sole .	14 8	5,422	100,362	.. June 13.
Tench .	40 0	—	383,252	.. May 28.

From this table it appears that there is no constant proportion between the weight of the fish and the number of eggs, or the weight of the roe. We have also no means of ascertaining any thing with respect to the relation between the size of the present fish and that of their progeny; as, for instance, we are unable to tell whether the fry that are produced from the roe of a small fish, are equal to, or greater or less than those produced by the roe of a larger fish of the same species, or the same age. We have also no means of ascertaining what proportion there may be between the eggs that are deposited and the number of fish that are hatched, and between the number that come to maturity. The eggs are eagerly sought after by other fishes, by aquatic birds and reptiles. In the young state, they are pursued even by their own species, as well as by beings belonging to other classes. But for the numbers of eggs thus produced, the very race of fishes would soon be extinguished by enemies while young; and we may add, that the diminution of the number of eggs would cut off a large supply of food, and destroy that dependence which

we observe in the system of nature, of the different races of animals on one another. The season at which fish deposit their eggs varies according to the species, and even the habits of the individual. It is well-known that among salmon, even in the same river, a difference of some months is observable, and we believe that the same remark is applicable to all other kinds of fish. In general, before spawning, fish forsake the deep water, and approach the shore, that the roe being placed in shallow water the influence of the solar rays may vivify it. At that season some fish forsake the salt water and ascend rivers; and, after spawning, retreat again to the ocean. The eggs of various species of fish belonging to the oviparous order, with distinct sexes, are used as articles of food. Where circumstances permit, they are consumed while in a recent state. In other situations they are salted, and form the well-known article of trade called caviar. The characters which the organs of reproduction furnish in the discrimination of species have been hitherto too much neglected. Connected as they are with the existence of the animal, and exercising a powerful controul over its habits, they ought to be examined with care, and their appearances recorded in detail. In the case of those fishes which are ovoviviparous, and range over the wide seas, not requiring to come to the shallow water for the purpose of depositing their eggs, this might be a matter of considerable difficulty, but much more might be recorded than has been done in the case of the spawning fishes; and they are not only the most numerous, but, in an economical point of view, by far the most valuable of the whole. We must, however, pay some little attention to another branch of the general subject.

**DISTRIBUTION AND MIGRATION OF FISHES.** These are subjects which cannot well be separated from each other by any analogies of the facts which we are capable of forming; and the observed facts are so few, and the connexion of them is so broken, that this is a portion of the subject upon which it behoves us to express ourselves with the greatest diffidence.

In order fully to see the causes of the distribution of fishes over the wide expanse of the sea in breadth, and through the depths of its waters in profundity, there are many elements required on which our information is very limited. We know that in the tropical waters the elements of life reach to a greater depth below the surface than they do in higher latitudes; and if there be any portion round either pole or poles, which is never clear of ice, we may presume that the number of fishes there is comparatively limited both in species and in individuals. Indeed, from all that we know of the matter, we may suppose that there is in the wide ocean of every latitude a depth beyond which no creature can live; and that, consequently, before such profound depths are reached, there must cease to be any fishes. But what this particular depth may be for any one latitude we have no certain means of ascertaining; because it must depend upon several circumstances, such as the solar action, in respect of latitude, the set of any current which may happen to pass over it, and the character of the bottom; not merely as respects the soil, or other substance of which it is composed, but as respects the action which may be going on under it. Thus, for instance, if a sea is in the vicinity of volcanoes, and especially if it is studded with volcanic islands, and subject to the production of new ones, there is no doubt that the water must be warmer, and also more subject to be put in motion in such a sea, than in one below which no

such sources of heat are in operation. Thus, for instance, there is no doubt that the Mediterranean, toward Sicily and the shores of Naples, is in some respects analogous to a seething pot; and the same may be said of the volcanic portion of the Red Sea; of the sea around some of the Atlantic islands; and, in short, of that around every land where there is volcanic action in the neighbourhood of the sea. If we could go minutely into this subject, which, however, is impossible from the want of the requisite data, we should find that the progressive history of fishes, and the progressive history of volcanic action, have a very close connection with each other. In former times, when the waters of the Mediterranean covered what are now the plains of Languedoc, and many of the summits of the central mountains of France were blazing with volcanic fires, a temperature equal to that at present under the equator may have been given to the waters of the Mediterranean; and this may have been the reason why, in the accumulations of fossil fishes, which are so remarkably plentiful in some parts of Italy, there are many species of which there are no types except in the tropical seas; and those shells and other productions of the waters, which are found in the Mediterranean, of more tropical character than anywhere else, under the same parallel of latitude, may perhaps be received as evidences of the same fact. We mention these few particulars, not with any intention of entering upon the investigation of a subject of such difficulty and uncertainty; but merely for the purpose of showing that if the history of the finny tribes could be properly worked out, it would throw much more light upon many of the most interesting points in geology than we at first would be apt to suppose.

In considering the distribution of fish, the first distinction, and the most obvious one which we are required to make, is that of fresh water and salt water fishes. That there is any permanent structural adaptation to any of these kinds of water rather than the other is rendered doubtful by the fact of some fishes living by turns in the one and in the other, and apparently keeping their health equally well in both. We cannot adduce a more striking or more interesting instance of this than that of the salmon, with which every one is so familiar in our own country. Yet even in the salmon, the transition from the one kind of water to the other must not be immediate, otherwise the fish cannot live; for a salmon which has been habituated to fresh water, will die of suffocation if instantly put in sea water; and a sea salmon will do the same if instantly put in fresh water. When, however, the transition is made gradually enough, the fish not only sustains no injury, but it appears, and is indeed, evidently part of the economy of its nature to make this transition. Not only this, but we believe, in some instances, fishes which are never naturally found in fresh water, but always in the sea, and that at considerable depths, have been brought to live in water scarcely, if at all, impregnated with salt.

The next distinction of fishes, with regard to locality, is into *littoral* and *pelagic*, or those which frequent the shores and shallows only, and those which are discursive through the broad waters. The most remarkable distinction between these is, that the fishes of the shores and banks, like the mammalia of the savannahs or meadows upon land, are generally gregarious or found in extensive shoals, while the others have much less propensity to congregate in

numbers. It has been supposed by some, that when coast fishes entirely disappear both from the shores and from the surface of the water, they retire to a considerable depth, and remain there in a state of inaction; but the evidence in favour of this is far from complete, and the analogy is rather against it. If ever so numerous a shoal from the coasts were to spread themselves over the whole surface of one of the wide seas, it is quite evident that they might be so far asunder as that a ship on its passage might not observe one of them except by accident. The migrations of those fishes used to be very much misrepresented, especially in the case of herrings and some others, which were alleged to breed in countless numbers in the regions of the poles, and to come annually thence, for no reason that could well be explained, except as a bonus to the fishermen of more southerly latitudes. We know that when those fishes, whether herring, pilchard, mackerel, or any other which appear thus periodically, the milts and roes are in a progressive state; that as they remain these advance to maturity; and that if the attempt to catch them is too long protracted, they are found to have shed their spawn, or to be in the condition of what is called "shotten herrings," which are empty, lean, and unwholesome. The same applies to every other species of periodical fish with which we are acquainted. The probability, therefore, is that such fishes have little migration in latitude with the seasons, or rather that they have none at all; but that, if it be their habit to feed in the clear waters, and not on the banks as ground fishes, they make their way as the spawning season approaches for the nearest shore, if it happens to be adapted for their purpose. In proof of this, it may be remarked that they do not remain off the points, or hang in the currents, as if they were seeking the substances with which the latter are loaded, but that they frequent the estuaries, the bays, and other shallow indentations of the coasts, where the spawn which they deposit may remain undisturbed. In addition to this, we have the further proof of the countless myriads of the fry, or "soil" as it is called in the case of herrings, which is observed on many parts of our shores in the early part of summer, and which is sometimes overcome by violent action of the weather, and stranded in a close and extended stratum along the beach. This takes place on many parts of the coast where there are none of the fishes in the mature state, or at least where they are not generally fished for; and this proves that though these fishes may accumulate in such numbers as to make the capture of them a profitable trade at particular points only, yet that they contrive to range a great way in line along the coast for the purpose of spawning, but that, as is the habit with most animals, they perform this operation during the night, or at all events at times when they are not observed.

Whether, after these fishes have left the coast and dispersed themselves through the sea, it would be worth while to fish the depths for such of them as are net fishes, is doubtful; but it is highly probable that, whether their numbers would repay the labour and expense of their capture or not, yet they may be found at all times and at all seasons in those seas on whose shores they spawn, if sought for at a sufficient distance from the land. It is also doubtful whether the same fish spawns annually, or requires two or more years to recover its tone and bring forward its vast progeny; but probability is in favour of the

latter, and this probability is strengthened by the fact that, on some parts of the coast, after several kinds of fish, the haddock among others, have, generally speaking, left the fishing grounds, and the few that remain are "run," "shotten," and out of season, the fishermen have only to stand some ten, fifteen, or twenty miles from the shore, according to the nature of the bottom, and their industry is rewarded by fish as abundant and in as good condition as ever.

On some places of the coast too, where the fishermen have a little speculation, and will listen to general principles (for, generally speaking, they are a superstitious and dogged race, and can hardly be driven from an old custom, however absurd and injurious to their own interest it may happen to be), they are enabled, so to express it, to go out and meet the fish, and thus bring them to market much earlier and in better condition; nor is there any doubt that, if duly sought for, all the fish which come seasonally upon the shores of any country might be found in good condition in some parts of the surrounding seas at every season of the year. Whether this may be the case with bottom fishes, which never come close in shore to spawn, unless the depth there bears some correspondence to that over the banks on which they generally reside, it is not so easy to say, because, as they of course, in the case of their moving shoreward to spawn, take the bottom sooner or farther from the land, they are not so easily or so frequently observed. It is probable that when we come to those fishes which are absolutely ground feeders, there is very little migration for the purpose of spawning, but that they rather deposit their spawn in the banks and shallows which they habitually frequent; and as those banks, instead of being swept bare by the tide, are places of deposit for those substances which are carried in the waters of tides and currents, it is highly probable that a much smaller proportion of the spawn of such fishes is destroyed, than there is of that of those which inhabit nearer to the surface and deposit their spawn in the shallows. The quantity of the latter which must annually be destroyed by birds, by young fishes, by crustacea, and by many other creatures which inhabit the margin of the sea, must be greatly beyond what we might suppose, and thus it is not easy to say how many races of animals may be in great part supported by the excessive production of the roe fishes, and yet leave a sufficient number of those animals themselves.

There is no doubt that the circulating currents which are put in motion by the rotation and revolution of the earth, and the different actions of the sun and moon at different times of the day, and different seasons of the year, have a considerable effect upon the seasonal distribution of these fishes which come within their range, and inhabit near the surface of the waters. But we have hardly space left even to glance over the outlines of this; and even if we had, the subject is beset with very many difficulties. We do not know the depth to which those currents extend, or how the counter currents may act under them; but it is very probable that the profound depths of the great oceans are not disturbed by any of them, or even that they have much effect in changing the abodes of the still deeper inhabiting fishes, especially those of the tropical ones, where, as we have said, fishes inhabit to a greater depth than they do in the colder latitudes. But it is natural to suppose that when any of these are caught by the current and

borne into colder latitudes, that they gradually come nearer and nearer to the surface, and thus a stray fish may accidentally be found on the shores of a temperate country, which is found only in the deep in warm latitudes. We may further suppose that those strays will be found most frequently at or near the point of confluence, where two opposite points meet, or in the embayments of a shore, along which a current sweeps when approaching the point of confluence. This seems to be the reason why there are so many fishes on the south-west coast of England, which are rarely, if ever, met with on any other part of the British coast, and also why such fishes occur (though more rarely) on the shores of the more southerly of the western isles of Scotland, than on the east coast. A similar cause appears to bring the more northerly fishes to the north-west of Scotland, and through between the Orkney and Shetland islands, and so along the greater part of the east coast, in numbers far greater than they are met with on the west; and if we inform ourselves well of the directions in which those currents set, and the seasons in which they act with the greatest force, we shall be in a condition for understanding what may be called the involuntary migrations of fishes.

But notwithstanding those currents, it does not appear that a very great number even of the surface fishes follow them far out of their own seas. From the islands which lie at the south point of America, there is a counter current eastward produced there, though it is probable that out at sea, clear of the islands, the general current is westward. But notwithstanding that there is thus apparently a facility for the movement of fish both ways, it has not been ascertained that there is a very extensive exchange of fish in this way between the Atlantic and the Pacific. So also there does not appear to be any very great interchange between the Atlantic Ocean by the Cape of Good Hope; nor between the Indian Ocean and the western Pacific, either to the southward of Australia or through the passages between that great island, and the south point of the Malay peninsula, broken and interrupted as those passages are by the numerous islands which lie between. It would, however, require far more information than we at present possess, or are likely ever to obtain, to arrive at even the elements of those vast movements of the ocean, and their effects upon the ocean's inhabitants.

The peculiar manner in which the tide circulates in the Atlantic, and the portion of comparatively "slack water," as it is technically called, which is the middle of the space round which the current circulates in that ocean, has no inconsiderable effect upon the distribution of the fishes which inhabit it. In this central space there is something analogous to a floating island, only it consists entirely of aquatic plants, and plants which are never at any time rooted at the bottom, but which derive their nourishment by floating in the water, in the same manner as the duck weed (*lemna*) which mantles our stagnant pools and ditches with green in the summer. This great float of aquatic plants is known to sailors by the name of the "gulf weed;" and though it is unconnected with the bottom, it covers a vast extent, and excepting that it shifts a little northward and southward, seasonally, the great mass of it remains pretty stationary. This floating weed is a grand nursery for marine animals, not a few of which, especially the *medusæ*, are poisonous, and seem to impart that character to the

fish which feed upon them; but still this sea-weed forms a lodgment for very many of the floating mollusca and crustacea, and offers a convenient place of attachment for the spawn of the pelagic fish, the fry from which again furnishes abundant food for other fishes, and also for aquatic birds. This weed does not lie wholly quiescent; for the boundaries are everywhere put in motion by the current, so that the greater part of the mass may be said to revolve on a sort of centre. There is a similar accumulation and current, though from the position of the shores the set of it is different, in the south Atlantic; and though the Pacific is too extensive, and has been too seldom visited for enabling us to judge with accuracy of its general phenomena, yet it is highly probable that there are similar accumulations of sea-weed there which are tenanted by similar classes of animals, and visited by fish in the manner that has been described.

We cannot, however, enter farther into this most interesting, but very extensive and exceedingly difficult subject; and we have thrown together these few particulars, more with a view of drawing the attention of general readers to the wonders and the wealth of the all-productive sea, than from any hope of communicating in a few pages, anything like substantial information upon a subject, the full development of which would form materials for the volumes of a library. We shall close this desultory article with a short outline of Cuvier's

**ARRANGEMENT OF FISHES.** The great primary division is into two sub-classes: osseous fishes, or fishes strictly so called, which are justly regarded by Cuvier as the typical ones; and cartilaginous fishes, or *CHONDROPTERYGII*, under which word some account of their general characters will be found. With regard to the osseous fishes, which are by far the most numerous, they will hardly require a notice in any separate article; but the distinguishing characters of the divisions of them will be found under the names referred to in the subsequent part of this article. The two divisions now mentioned may be considered as sub-classes; and Cuvier divides each sub-class into several orders, each order into families, and each family into genera and species. Referring to the article above named for the families of the cartilaginous fishes, which form only one order, and admit of arrangement into three families, we shall now consider the list of fishes, properly so called.

These Cuvier arranges into six orders: *Acanthopterygii*, *Malacopterygii*, of which there are three orders, formed from the position of the abdominal fins, *Lophobranchii*, and *Plectognathi*. Of the first of these some notice has already been taken, and reference made to the several sub-divisions in the article *ACANTHOPTERYGII*, to which the reader is referred, so that we shall have to notice here only the remaining five orders, which we can do more effectively, and probably in much shorter space, than if we were to devote a separate article to each.

It will be perceived that this arrangement is not founded on the same character or part of the organisation throughout all the orders; and thus there may appear to be an imperfection about it which is not observable in the more artificial systems of others. But, notwithstanding this, each order is founded upon that structural character which is the most conspicuous; and, therefore, the arrangement is, perhaps, the best which, in the present state of our knowledge, can be made.

It would, perhaps, have given a little more neat-

ness to the system if it had been possible to find a third name, founded upon some common character of Cuvier's last two orders of bony fishes; but these are so unlike each other, and all the rest, that this would not be an easy matter. Could it be done, the true fishes would stand in three distinct divisions; two of them named from the textures of the fins, or rather of the rays of the fins, and the third of some character which is not made out in the mean time; so that at present, besides the *ACANTHOPTERYGII*, referred to above, there are three divisions; and the first, and by far the most numerous of the three, is divided into three orders, according to the position of the fins, as already stated.

*MALACOPTERYGII ABDOMINALES* have the fins with all the rays soft or jointed, and the two posterior fins on the under part placed far backwards, near the vent, so that in them the position of the four fins, which answer to the extremities of mammalia, have nearly the same relative plane on the body that the four legs have on these. This position indicates the same sort of motion as that of the mammalia, namely, motion in nearly the same plane without much ascent or descent; or that the fishes are straight-forward swimmers, inhabiting the waters at no great depth. They comprise by far the greater number of the fresh water fishes, though some of them are also inhabitants of the sea; the whole family are valuable as food: and some of them are in this respect among the most choice of the finny race. Generally speaking, their gill-openings are large, their gills perfect, and their respiration considerable; they do not, so far as we know, inhabit the waters at any very great depth; and with very few exceptions they die very soon after being taken out of their native element. There is a correspondence in the general form of the body to their habits, which renders them a very natural order. They are spindle-shaped, or with long and tapering bodies, a little compressed, but still oval in the section, with the lateral line straight, the muzzle in general small and neat, and the centre of gravity not very far from the centre of the length. In their shape, indeed, they are, perhaps, the most handsome of all the fishes; and as, from their abundance in the fresh waters, people have been more familiar with them than with most of the others, they are, perhaps, the typical fishes with most people; and when we think of a fish, it is a form such as that of one of these which first suggests itself to us. The order is divided by Cuvier into five families.

*The Carp family (Cyprinoides).* These are almost all fresh water fishes, some of them are found in mountain pools, where they can hardly be supposed to have come from any other waters; and there are a few which are capable of making short journeys on land. The opening of the mouth is in general but shallow, and the jaws have no great strength; these jaws are often without teeth, and the margin of the mouth is formed by the intermaxillary bones. To compensate for the want of teeth in the margin of the mouth, the bones of the pharynx are in general abundantly toothed. The number of rays in the gills is but few; the body is scaly; they have no adipose or fatty dorsal fin, as we find in the silures and the salmon; their stomach is a simple cul-de-sac; there are no cæcal appendages to their pylorus; and they are, perhaps, the least carnivorous of all fishes.

*The Pike family (Esocæ).* Many of these are also inhabitants of the fresh waters, but some of their characters and their dispositions are very different

from those of the former family. They have no adipose fin on the back; the margin of the upper jaw is formed by the intermaxillary bones; and the lower jaw is furnished with very large and formidable teeth. They are exceedingly voracious fishes; many of them are found in the salt waters, but others inhabit the sea; all have an air-bag; and with very few exceptions they have the dorsal fin far back, or immediately over the anal. The common pike may be regarded as the typical fish of this family.

*Family of Silures (Siluridæ).* These are distinguished from all the rest of the order by the absence of true scales, having only a naked skin, or that skin covered in some place with bony plate. Their intermaxillary bones are suspended from the ethmoid bone, and from the margin of the upper jaw; their maxillaries are small, or they are produced in fibrous appendages. The intestinal canal is ample, with convolutions but without cæca; the air bag is large and attached to a peculiar apparatus of bones. The dorsal and pectoral fins have often one strong articulated spine as the first ray, and many of the fishes have an adipose or fatty fin, the same as in the salmon. Generally speaking, they inhabit the fresh waters, are rather sluggish fishes, and attain a large size, but their flesh is not held in the highest estimation.

*The Salmon family (Salmonidæ).* This family is so interesting in very many of the genera that we shall have occasion to treat of it somewhat at length in an article *SALMON*, so that in the mean time we shall merely mention that in this family the body is scaly; there are in general two dorsal fins, the first with soft rays, the second very small, and adipose or fatty, to appearance without any rays; they are furnished with an air bladder, many of them inhabit the fresh waters and others ascend the rivers; they are in general very voracious fishes, and their flesh is held in great estimation.

*The Herring family (Clupeæ).* This is also a most interesting family, and will require a separate notice under the article *HERRING*, so that we need not enter into many particulars in the mean time. No species of this family has an adipose fin on the back; the upper jaw is formed as in the trout, of the intermaxillary bones in the middle, and the maxillaries at the sides, the body is scaly in all the species, and the scales are often very silvery and shining; they, in general, have an air-bag, and numerous cæcal appendages to the intestines. Most of them are inhabitants of the sea, but some are met with in the fresh waters and others ascend the estuaries of rivers.

*MALACOPTERYGII SUBERACHIATA.* The general character of this order is the abdominal fins situated immediately under the pectoral, or immediately in advance, or in the rear of them. In every instance, however, all the four fins are articulated to the same bones, namely, the bones of the shoulder; and thus the power of changing its direction in motion, is concentrated upon the fore part of the fish. In those species which have nearly the form of those of the preceding order, the head is very much enlarged, and the eyes, and, generally speaking, the gape, and also the gill-openings, are much larger in proportion. The whole of the order are ground fishes, or they, generally speaking, inhabit deeper water, and find their food at or near the bottom. Most of them are sea fishes, but some are found in the fresh waters. Their flesh is, generally speaking, white, and very much prized as food. There are three families in the order.

*The Cod family (Gadoideæ).* This is one of the

most important family of fishes; and, therefore, we shall have to give some account of it under the specific name, when we shall bring together the principal genera, in order that we may give an account of them in the shortest space possible.

*Flat-fish (Platorideæ).* These are also very important fishes in an economical point of view, being very abundant, readily caught, and much esteemed for their wholesome and nutritious qualities. As there is no scientific name generally used for them, we shall give some notice of the principal genera and their characters, in the article *FLAT-FISH*.

*Discobolus.* This order has no general English name; and the scientific one is derived from the peculiar form of the ventral fins, which form a disc under the thorax. The order is not a numerous one; and the different species which compose it are more curious than useful. Some account of them will be found in the articles *LEPADOGASTER*, *CYCLOPTERUS*, and *ECHENEIS*.

*MALACOPTERYGII APODA.* Fishes of this order have the ventral fins entirely wanting, and, therefore, they are less fitted for ascending and descending in the water than almost any other fish. They form but one family, *Anguillidæ*, in all of which the body is elongated. Notices of the principal genera will be found in the articles *ANGUILLA*, *EEL*, *SACCOPHARYNX*, *GYMNOTUS*, *GYMNARCHUS*, and the different subordinate articles referred to from the one or the other of these.

*LOPHOBRANCHII.* This is a small but a singular order, the leading characters of which are, that the jaws are complete, and free or articulated, though of peculiar shape. Their principal character, and the one after which they are named, is the structure of the gills, which are not in regular fringes, like those of the generality of fishes, but formed into a sort of tuft, which are placed in pairs upon the branchial arches, and each individual fibre is divided or toothed, something in the form of a comb. These gills are attached to a large gill-lid, but there is only a small hole for the escape of the water. Their bodies are in general covered with a coat of mail consisting of scaly pieces; they are generally of small size, and their bodies contain little or no flesh. There are only two leading genera, *Syngnathus* and *Pegasus*, under which name some account of those very singular fishes will be found. From the singularity of their forms, they are called sea-needles, sea-horses, and a number of other names.

*PLECTOGNATHES.* These form the last order of bony fishes, and make a very near approach to the cartilaginous ones. The name of the order, as every one knows, signifies that the different bones of the jaws are soldered or united to each other. This distinguishing character is having the maxillary and intermaxillary bones united to each other, and the whole of the palatal arch attached in like manner to the bones of the cranium; but the whole of the bones are soft and flexible, intermediate between the rest of the bony fishes and the cartilaginous ones. The gill-lids are little else than thick skin; and the gill-openings are merely slits. The true ventral fins are entirely wanting. Cuvier divides them into two families which are exceedingly natural, *Gymnodontes*, and *Sclerodermes*, which are named from the peculiar way in which the jaws are armed, and of which some account will be found under those titles. Generally speaking, they are fishes of very singular form, probably the most so of any of the finny tribe. Such is a

very short outline of the systematic arrangement of fish by the illustrious Cuvier; and with which we shall close our desultory notice of this highly interesting, and truly valuable class of animals.

*FISSIROSTRES (Open-billed birds),* one of the sub-orders, or families, into which Cuvier divides the great order *Passeres*. Its general relation to the class will be seen by referring to the article *BIRD*. It is rather a small family, but the characters of the birds which compose it are peculiar. The bill is short, very broad, flat, slightly curved, and deep in the gape, and the tomia do not meet at the sides. The bill is without any notch in the mandible, which is the chief distinction between these birds and some of the fly-catchers. They feed wholly upon insects, and are migratory. There are only two distinct divisions: day-feeders, which form the different swallows and swifts; and night-feeders, which comprises the birds usually termed goatsuckers. Some of the details will be found in the articles *GOATSUCKER* and *SWALLOW*.

*FISSURELLA (Lamarek; PATELLA, Linnæus).* This shell exhibits a very striking illustration of the wisdom of the present system of classification, since it differs in many important features from the patella, with which Linnæus had confounded it; taking in this, as in every other instance, the form of the shell, without any reference to its parent architect. Shells of this genus are in the form of a very depressed truncated cone, oblong or elliptical, and perforated at the summit, vertically towards the anterior part; the orifice is in connection with the animal's mantle, and never quite circular, but more frequently long, and oval-shaped, and sometimes resembling a key-hole, whence they are familiarly called *key-hole limpets*. The margin of the shell is thickened, and sometimes crenulated, and the exterior surface longitudinally ribbed, and sometimes striated transversely. There are numerous species of this mollusc: they will admit of a better defined arrangement than now exists.

*FISTULANA (Lamarek.)* All former naturalists considered these tubes, like those of the *Aspergillum* and *Clavagella*, which enclose and protect the animal, to be the shells themselves, but it is now satisfactorily ascertained that they are quite distinct, that genus having their shell free and detached within the sheath or external tube. This shell is bivalve, and neither of its valves fixed into the partition of the tube, which is generally testaceous, closed, and retort-shaped at the anterior end, attenuated towards the other extremity, where it is open. If the shell contained have its valves similar, but not closing together, they are what is termed gaping. The posterior open extremity is divided by a thin partition, forming internally two channels or siphons.

The animal greatly resembles that of the teredo, but is in general shorter and more club-shaped, and a great diversity of opinion exists as to the propriety of separating this genus from that, since it has been asserted that the *Fistulana* has been found embedded in wood, which it was not supposed capable of effecting, and therefore a good ground for constituting a new genus. Two fossil species are known.

*FISTULARIA.* See *PIPE FISH*.

*FLACOURTIANCÆ* is a small natural order of equatorial shrubs or small trees, with alternate exstipulate, simple leaves, shortly petiolated, often entire, and coriaceous: flowers are axillary, solitary, or congested, and they are regular and usually united, but sometimes separate by abortion. The calyx is

composed of from four to seven sepals, slightly attached at the base. Petals equal in number to the sepals, and placed alternately with them. The stamens are equal to the sepals in number; and occasionally changed into nectariferous scales; anthers free and two-celled. Germen free, roundish; sessile one-celled, ovules many. Fruit is one-celled, baccate or capsular, and filled with a soft pulp.

*Flacourtia ramontchi* is the Madagascar plum, so called from the resemblance of its fruit to ordinary prunes. The fruit of other species, such as *F. sapida*, *inermis*, *sepiaria*, *cataphracta*, &c., are also eatable, and the young shoots of the latter, which have an astringent bitter taste, are esteemed as a good stomachic medicine.

**FLAMINGO** (*Phenicopterus*). A very peculiar genus of birds, forming one of the groups which Cuvier has brought together, as detached from his regular division of *Echassiers*, or stilt birds, and which indeed differ so much from all other birds in some particulars, that they form a very small but very peculiar group, which can neither be classed with any of the rest, nor described by any common character. Cuvier himself describes the flamingo as "one of the most extraordinary and most isolated of all birds. The legs, of an excessive length, have the three front toes palmed to the end, and the hind one extremely short. The neck, not less long nor less slender than the legs, and the small head supports a bill, whose lower mandible is an oval, bent longitudinally into a semi-cylindrical canal, while the upper one, oblong and flat, is bent crosswise in its centre to join the other exactly. The membranous foss of the nostrils occupies almost the entire side of the part which is behind the transverse bend, and the nostrils themselves are a longitudinal cleft of the lower part of the foss. The edges of the two mandibles are furnished with small and very fine transverse laminae, which, joined to the fleshy thickness of the tongue, gives to these birds some analogy with the ducks. The flamingos might even be placed among the palmipedes, but for the length of the tarsi and nakedness of the legs. They live on shell fish, insects, and fishes' eggs, which they get by means of their long neck, and by turning their head round to employ with advantage the crook of their upper bill. They build in the marshes a nest of raised earth, on which they rest astride to watch their eggs, as their long necks hinder them from adopting any other position."

The generic characters are: the bill thick, strong, higher than broad, toothed, conical towards the point, naked at the base, upper mandible abruptly inflected, and bent down on the under at the lip; the under broader than the upper; nostrils longitudinally placed in the middle of the bill, and covered by a membrane; legs very long, with three toes before, and a very short one articulated high on the tarsus behind, the fore toes connected by a web which reaches to the claws; wings middle-sized.

The principal species of this singular genus, the **RED FLAMINGO** (*Phenicopterus ruber*), of which the general colour is red, and the quills of the wings deep black, or if there be two, as is stated by some ornithologists, they appear to be but little different, except in size. The bird when full grown is not so big as a goose in the body, but it has the neck and legs longer in proportion to its general size and weight, than those of any other bird. The length from the tip of the bill to the extremity of the tail is

about four feet, or only three or four inches more; but when the legs are stretched out, the length from the bill to their extremity exceeds six feet. The

Flamingo.

neck is slender, and of an immoderate length; the tongue, which is large and fleshy, fills the cavity of the bill, has a sharp cartilaginous tip, is furnished with twelve or more hooked papillae on each side, which bend backwards, and has a ball of fat at the root, which epicures reckon a great delicacy. The bird, when in full plumage, which it does not attain till its fourth year, has the head, neck, tail and under parts of a beautiful rose red, the wings of a vivid or scarlet red, the back and scapulars rose-red, and the legs rosaceous. The young, before moulting, have their plumage cinereous, and a considerable portion of black on the secondaries of the wings and tail; at the expiration of the first year, they are of a dirty white, with the secondaries of the wings of a blackish brown, edged with white; the wing-coverts at their origin white, faintly shaded with rose colour, but terminated with black, and the white feathers of the tail irregularly spotted with bluish brown. At two years of age the pink on the wings acquires more intensity. In all places of the world where flamingos are met with, they are highly interesting and characteristic birds, their great extent, their singular shape, their brilliant colours, and the sunny skies under which the generality of them sport over the broad waters, are all calculated deeply to interest, and widely to gratify the observer of nature. They are, generally speaking, birds of warm climates and rich places; but they are not wholly confined to the regions within the tropics. They are met with in the warmer parts of the continent, but they do not appear in any case to range more polarly than about the fortieth degree of latitude. They are common on the African coast, and the islands adjacent to the Cape of Good Hope,

and sometimes on the shores of Spain, Italy, Sicily, Sardinia, and even at Marseilles, and some way up the Rhone, but rarely in the interior of the continent of Europe, and seldom on the banks of the Rhine. We trace them on the Persian side of the Caspian Sea, and thence along the western coast as far as the Wolga. They breed abundantly in the Cape de Verd islands, particularly that of Sal, constructing on the sea shore, but so as not to be flooded by the tide, a nest of mud, in the shape of a pyramidal hillock, with a cavity at the top, in which the female generally lays two white eggs of the size of those of a goose, but more elongated. The structure is of a sufficient height to admit of the bird's sitting on it conveniently,

Flamingo.

or rather standing astride, as the legs are placed, one on each side, at full length. The female will also sometimes deposit her eggs on the low projection of a rock, if otherwise adapted to her attitude during incubation. The young are not able to fly till they are grown ; but they can previously run with wonderful swiftness. In this immature state they are sometimes caught, and easily tamed, becoming familiar in five or six days, eating from the hand, and drinking freely of sea water. But they are reared with difficulty, being very apt to pine from want of their natural subsistence, which chiefly consists of small fishes, and their spawn, testacea, and aquatic insects. These they capture by plunging the bill and part of the head into the water, and, from time to time, trampling upon the bottom to disturb the mud, and raise up their prey. In feeding, they twist the neck in such a manner, that the upper part of the bill is applied to the ground. They generally shun cultivated and inhabited tracts of country, and resort to solitary shores, and salt lakes, and marshes. Except in the pairing season, they are generally met with in large flocks, and at a distance, appear like a regiment of soldiers, being often arranged in file, or alongside of one another, on the borders of rivers. When the Europeans first visited America, they found these birds on the swampy shores quite tame, gentle, and noways distrustful of mankind ; and we learn from Catesby, than when the fowler had killed one, the rest of the flock, instead

of attempting to fly, only regarded the fall of their companion in a sort of fixed astonishment, so that the whole flock were sometimes killed in detail, without one of them attempting to make its escape. They are now, however, extremely shy, and one of them acts as a sentinel when the rest are feeding ; and the moment that it perceives the least danger, it utters a loud scream, like the sound of a trumpet, and instantly all are on the wing, and fill the air with their clamour. Flamingos when at rest, stand on one leg, having the other drawn up to the body, and the head placed under the wing. When flying in bands, they form an angle, like geese, and in walking they often rest the flat part of the bill on the ground, as a point of support. These beautiful birds were held in high estimation by the ancient Romans, who often used them in their grand sacrifices, and sumptuous entertainments. Pliny, Martial, and other writers, celebrate the tongue as the most delicate of eatables. The flesh is not despised, even in modern times ; but it is alleged by some of those who have partaken of it that it has an oily and somewhat muddy flavour. That of the young is generally preferred to that of the adult bird. The aerial march arrival, and the general movement of these birds, are described as being particularly splendid. From the high bastion which forms the promenade at the city of Cagliari, they are seen moving like lines of fire along the heavens. Those lines sometimes move on in regular order and with uniform flight ; at other times the line halts, or performs a slow wheeling circular or spiral course, until they have arrived at the point where they are to rest. Nor does the beauty of the spectacle cease after the birds have alighted on the ground ; for they march and wheel and perform various operations there with nearly the same order and regularity as soldiers go through their evolutions at a well conducted review. Indeed, from their great and almost equal powers on the wing and on foot, these birds are equally interesting in the air and on the earth.

**FLAT-FISH (*Pleuronectes*).** One of the divisions of those soft-finned fishes which are *sub-brachial*, or have the ventral fins under the pectorals, and a very curious, interesting, and valuable tribe of fishes ; while their numbers in those localities which they frequent, and the very general distribution of those localities over the earth, tend greatly to increase both their interest and their value.

Of the bony fishes, leaving the cartilaginous ones out of the question, in which, however, the rays or skates bear a considerable resemblance to the true flat-fishes, these last may be regarded as the lowest inhabitants of the sea, and in this respect distinct from the others. They do not indeed dwell in the greatest depths in absolute measurement, for there are some of the other fishes having the head, and especially the eyes, remarkably large as compared with the rest of the body, that are found in deeper water than any of the flat-fishes. The flat-fishes, however, whether the waters which they inhabit be deeper or shallower, are more true to the bottom, and less prone to range than any other fishes with which we are acquainted.

We need hardly mention that the different species of flounders, soles, turbot, halibut, and several others, which get different names in different parts of the country, are the fishes to which we allude, for these are so plentiful in all our fish markets, that their general appearance and form is known to everybody,

Their manners are, however, worthy of some attention. If we could take a type for sea animals from the animals of the land, we might be inclined to say, leaving difference of food out of the question, that these flat-fishes hold nearly the same place in the waters of the ocean that the ruminant mammalia do on the land. It is true that none of them feed on the vegetable productions of the sea, for the fishes which do so have the body placed with its breadth in a different direction, and they are all fishes inhabiting near the surface, and, generally speaking, found only in the warm latitudes. But still the flat-fishes inhabit what may be considered as the fattest pastures in the sea—namely, those bottoms of mud and ooze within a moderate range of depth, and also at similar depths where the bottom is soft sand; but in general they are not found in stony places or among rocks, and it is probable that there are none of them in situations where the bottom is at any very great depth. It is of course not possible to state in general terms the distance from the shore at which the favourite abodes of those fishes either begin or end, because the difference of depth, and the character of the water off shore vary so much, even within a limited extent of coast, that each place must be determined by actual observation. In general, however, they have their chief resorts in those places where currents meet and deposit banks, or where the current of a river and the water of the sea act and react upon each other at the bottom in the course of the tides. Some of them, as will be more particularly explained when we notice the species, are much more landward than others, and found not only in the shallow parts of the sea near the shores, but in some of the species in the rivers and lakes of fresh waters. This is the case with the flounder branch of the family. The soles, which are perhaps among the least discursive of any, are generally found in currents, and in the estuaries of rivers, from about ten to twenty miles distant from the land, according to the nature of the ground; but when the shores are very steep and rocky, and have deep water at their bases, no such fish are found, and it is probable that the accumulation which is found at the bottom of such places consists of matters which are not only dead, but in such a state of decomposition as to be reduced to their merely saline and earthy ingredients, and therefore unfit for being the food of any animal.

In those haunts which are congenial to them, the flat-fishes are understood to keep very near the bottom, and to have part of their bodies buried in the soft sand or ooze, with only the head exposed. Their form is remarkably well adapted to this habit, and it is a form which differs greatly from that of any other vertebrated animal.

In respect of the general action of their bodies, the flat-fish still preserve the typical form of a fish, that is, the action of the spine is lateral with regard to the true mesial plane of the great mass of the body, and different from all the land vertebrated animals which have the principal action of their spine vertical as respects this plane. In the flat-fish, however, the plane of the body is turned, so that instead of swimming with the back uppermost and the belly undermost, as is the case with other fishes, they swim upon the side, and with both edges of the mesial plane equally produced through the greater part of their length, and only with the cavity of the body, which is generally very short in the extended part, turned a little to

one side, and the top of the head turned a little to the other. From this form the whole fish is enabled to swim as one continuous flattened body, while the eyes, which are generally very small and close together, are on the upper surface, the mouth being placed more or less obliquely to one side or other of the snout, and the fins, which answer to the extremities of quadrupeds and birds, placed on the upper and under sides, though also a little obliquely. Generally speaking, the kind of colour and also texture of skin which characterises the whole back of any other fish, is confined to the side of the flat-fish in which the eyes are situated, and the other side, which is never turned up in swimming, is always white. There are some species, however, in which both sides are covered nearly in the same manner, but there is none in which both eyes are not on the same side of the head, as estimated from the position in which the fish swims.

If the skin is removed, it is found that, though the upper and under sides are not quite the same in their muscular texture, or in their quantity of muscular substance, yet that they have a very near resemblance to each other in the arrangement of their fibres. The principal action of the body consists in bending the spine downwards, that is in giving it a concavity at the middle of the under side, and in some of the species this motion appears to be so differently communicated to different parts, that there are several contrary flexures of the spine at the same time. It does not appear that the spine of these fishes is capable of much motion laterally, or that the last is with them the chief organ of progressive motion, as it is in other fishes. The tail can only strike the water upward or downward, and therefore is effective more as a means of ascent and descent than of forward motion.

It is with the side or lateral fins, answering to the dorsal and anal fins of an ordinary fish, that the progressive motions of flat-fishes are effected. These fins, no doubt, strike the water upward or downward, and not laterally; but then the bendings which are produced in the body, and in the extremities of these fins, produce a progressive motion, though it is slower, and performed with much more labour in proportion to the effect than in other fishes; because, while the bodies of these fishes are curved vertically in swimming, the different parts of them are subjected to different pressures of the water, and a portion of the action is taken off by the resistance of the other part of the bend. The pectoral fins are rather small in most of the species, but the dorsal and anal are continued throughout nearly the whole lines of the sides, or rather of the ridge of the back and under part of the body, for these are the true situations of the swimming fins of the flat-fish. When the fish is laid down with its eyes upward, its natural position in the water, that fin which is on the same side with the eyes is to be considered as the dorsal fin; and the one on the opposite side, where the mouth, the gill-openings, and the vent are met with, is to be considered as the anal fin. In most of the species the pectorals are situated just in the rear of the upper angle of the gill-openings, and the ventral fins in advance of these, near the commencement of the anal fin, and partially twisted a little from the side in which the eyes are. These four fins are, however, as we have said, very small in size, and they cannot be very efficient in any motion

of the fishes. It is in consequence of having those marginal fins along what appear from its position in the water the two sides of a fish of this kind, that the name of *Pleuronectes*, or "swimmers by means of the sides," was first given to those fishes by Artedi. This name is certainly founded upon the most remarkable structural character of these fishes, and therefore it serves well enough for distinguishing them from other fishes; but if we are to consider the side of a flat-fish as having the same position with regard to the spinal column which the side of any other fish has, then it is not by means of fins attached to the sides, but by fins attached to the ridge of the back and the middle of the belly, that those fishes perform their principal motions in swimming.

Flat-fishes have the head small, and also short, in proportion to the whole volume of their bodies; the opening of their mouth is also small, and the teeth very minute. Their gills are rather contracted, and in many species the gill-lids consist of only a single piece. There are six rays in the gills, but their whole volume is small as compared with that of the fish, so that their quantity of breathing must be limited. The cavity of the body is very small and short, but it is prolonged in small sinuses toward the tail. They have no air bladder; and, indeed, if we are to adopt the common opinion, and suppose that this viscus has anything to do with the change of specific gravity, and consequent ascent and descent of the fish, we might conclude that such an apparatus would be quite superfluous in those flat-fish, inasmuch as their most powerful action in swimming is an ascending or a descending one. They, however, do not avail themselves much of this, as they seldom rise far from the bottom, and their motions, when they do rise, are very slow and wriggling. They cannot, indeed, make much way without so much flexure of the body, as exposes a considerable portion of their white sides, and thus renders them very conspicuous objects to those fishes which prey upon them, and they are the chief food of several species of the voracious cartilaginous fishes.

In general they remain placidly on, or near the bottom, sometimes with only a little portion of the upper surface of the head exposed, and then their colours on the upper part are generally so similar in colour to sand and mud, that their enemies have some difficulty in finding them out. Many of them are very prolific: the spawn of the common flounder, for instance, containing little short of a million and a half of germs; nor is it unworthy of remark that there appears to be in this class of fishes a considerable correspondence between the powers of production, and the absolute numbers and distribution. The sole, for instance, which, though abundant in its localities, is a much more local fish than the flounder, does not produce above a tenth of the progeny; and this gives us some reason for thinking that, though we are not in possession of all the elements necessary for the full establishment of the fact, there is a good deal of correspondence between the productive power of fishes, and their actual numbers.

Nor can we fail to admire the great degree of concealment which those fishes derive from their shape and colour. When they are on the bottom, it is not very easy for any other species of fish to see them or to seize hold of them even if they should; and they themselves are, on the other hand, placed in the very situation in which they can use their eyes with the greatest possible advantage, both in finding their own

food, and in escaping from becoming the food of their more powerful neighbours. Their forms, their situation at the very bottom of the water, and all their habits, cut them off from almost every means of safety excepting concealment; for they have less scope for escaping, and are less fitted for availing themselves of the scope they have, than any other race of fishes.

From the character of the mouth, the smallness of the teeth, and the fact of some of the species having teeth only on one side of the mouth, it is evident that flat-fishes are not capable of taking prey of any great size. So also, from what has been said of the feebleness of their powers of motion, it must be evident that they are not adapted for giving chase to any animal which can get away from them, with even a moderate degree of speed. Still, the whole race are animal feeders, and in proportion to the extent of their powers, they are voracious. Indeed, fishes of all kinds are great feeders; and, though some feed upon minute substances, and others swallow fishes, much more nearly equal to their size than one would at first sight be led to expect, yet they all feed more greedily, and perhaps more largely than the majority of land animals. It is probable that the muscular powers of fishes are much less subject to fatigue than those of land animals; and though they spend a good deal of their time in a state of rest, either in the volume of the waters, or at the bottom, it is doubtful whether any of the species have a renovation by sleeping, at all resembling that of land animals. From the slowness of their motions, and the little range in distance which they require to undergo, it is highly probable that the flat-fishes have less muscular exertion than most others of the class; but as it is impossible to observe their habits with any minuteness, nothing very positive can be declared respecting them. In all probability their chief food consists of those molluscous animals, and minute fishes, which the tides and currents of the bottom carry along, and deposit on the banks, and other places where flat-fishes abound. That they do not feed upon any sort of ground animal, but on something which floats in the water over them, is proved by the position of their eyes, which are probably the chief organs in guiding them to their food. They very readily, however, take bait in small pieces, and though most of them prefer molluscous animals, a little bit of almost any fish will suffice. Those which ascend the estuaries of trouting streams are often very annoyingly deceiving to those who use bait in angling. The flat-fish catches very readily at the bait, and as the form and twisting up and down of its body, render it much more difficult to pull through the water than any common-shaped fish, the hope of possessing a trout four or five pounds in weight, changes into the actual possession of a flounder of not the same number of ounces.

There are a few difficulties connected with the natural history of flat-fish, as indeed there are with every fish, and more especially with every fish which keeps much below the surface. It seems too, that there are sometimes peculiarities in individual specimens of species which are well known, such as the head twisted the other way, or the sides of nearly the same colour. But still the general characters of the family are obvious and well marked, so that there is never any risk of confounding any one of them with a fish of any other kind. Considered as articles of food, there is great difference, and this applies not only to the quality, but to the quantity, of eatable matter

which there is, in proportion to the apparent size. We believe that the whole tribe are wholesome, though in some the flesh is too soft, and in others it is too hard for their being of much value; but upon the whole they may be considered as valuable fishes to man; so is the case with almost all bottom fishes. They are rather tenacious of life, though probably not so much so as eels; but they do not keep so long after they are dead as eels do, nor do they answer for salting. Taking all these circumstances into consideration, they may be regarded as forming a coast supply, rather than one which admits of being carried far into the interior. On the coast, however, if the bottom is favourable for them, they are found in great abundance, and some of them continue longer in season than most other species of fish; and this is the case most generally with those which are of the best quality, a circumstance which further increases their value in an economical point of view.

This family of fishes has been differently arranged by different describers and classifiers of the finny tribes; but in giving a short enumeration of the leading species, we shall follow the arrangement of Cuvier, which has the advantage of both accuracy and authority. According to this arrangement the great genus *pleuronectes* is divided into seven sub-genera; but the character, of which we have given a short outline, is pretty common to all those divisions. We have already mentioned the sixth and seventh of those sub-genera, in the article *ACHIRUS*, so that we have now only the remaining five to enumerate. These are *Platessa*, plaice, and flounders of different kinds; *Hippoglossus*, halibuts; *Rhombus*, turbot; *Solea*, soles; and *Monochirus*, which is nearly related to the ordinary soles in its general characters, only it has the pectoral fin on one side almost or altogether obliterated. The other two divisions, *Achirus* and *Pegasus*, are also soles, in which both pectoral fins are obliterated.

**PLATESSA.** The general characters of this sub-genus are: a row of blunted cutting teeth in each jaw, and very often flattened teeth on the pharynx; the dorsal fin reaches up only to below the upper eye. It, as well as the anal fin, is smooth, and there is an interval without any fin between each of these and the caudal. Their form is that of a lozenge or rhomboid, and most of them have the eyes on the right side of the head. They are common in most seas, and some of the species enter pretty largely into the estuaries of rivers. The most plentiful species is: the fluke, common plaice, or Dutch plaice, which is very abundant in the seas and waters which are not very deep, and have muddy bottoms. It is characterised by a row of six or seven tubercles, forming a line on the right side of the head, between the eyes; its colour above is olive, spotted with small dots of aurora red, and the under side is white. It grows to the length of about a foot, is understood to spawn about the month of February, and thus it is in season during great part of the year. It is obtained in greater numbers, and in more places of the sea than most of the others; but, though its flesh is wholesome when recent and in good condition, it very soon becomes tainted, so that there are more unwholesome plaice brought to market than almost any other fish. The mouth of this species is small, and has the lower jaw longer than the upper; the scales upon it are small, pressed deeply into the skin, and firmly attached. The general number of rays in the fins are seventy-two in the

dorsal, eleven in the pectoral, five in the ventral, and fifty-four in the anal.

The *Flounder* (*Platessa flesus*) is about the same size as the former, but differs in the marking of the body, and texture and appearance of the skin. In general the ground colour on the upper side is olive, marked with brown, and occasionally with intermediate patches of whitish, yellowish, or reddish, but it never has the same bright aurora spots as appear on the back of the fluke. There are small sharp spines along the lateral line, and at the junction of the dorsal and anal fins with the body; and the lateral line near the fore part is bent upwards. This is the least seaward of the whole family; and is often found at such a distance up the rivers as that the water has not the least taste of salt. It occurs most frequently, however, in rivers the feeders of which flow through rich soil, and thus deposit great quantities of mud and silt in the eddies of slow currents; and it is chiefly in such places that this fish is to be met with. The quality of its flesh depends a good deal on the water in which it is found; but though it is esteemed in those rivers which contain comparatively few fish of superior quality, it is not very superior to the fluke. From the number of situations in which the flounder is met with, it may be naturally supposed that there are many differences in respect to size and appearance; and it is also worthy of remark that though the generality have the eyes on the right side of the head, specimens are often found which have them on the left, and which evidently belong to this species. It is understood that this species, like the former, spawns in the winter; and therefore, like that, it is a summer fish for the table.

The *Dab* (*Platessa lemanca*). The common dab is nearly of the same size and shape as the fluke, but its mouth is wider, its eyes are larger, and so are its scales, which are rough or partially toothed in the margins. Its teeth are also more large and more pointed, standing in an even row in each jaw. The colour above is brownish, frequently mottled with darker blotches, and occasionally with whitish ones. It is a very common fish, spawning in May, and for this reason is in best season for the table, when the early spawners are "run" and unwholesome. Its flesh is perhaps not so delicate as that of either of the former two, when they can be obtained quite fresh and alive; but as it does not decay so soon, it is better for supplying markets far from the coast.

There are many other species of this genus which are less frequent upon the British shores, but their history is rather obscure; and it is not unlikely that an accidentally formed or coloured variety, especially when young, has been occasionally figured and described as a distinct species. A larger species is mentioned by Cuvier under the name of *Platessa latus*, which is much broader than the common ones, the breadth being equal to two thirds of the length, but very little is known respecting it.

All the species of *Platessa* are gregarious, collecting in considerable numbers on favourite spots, and seldom quitting these to range in the turbulent waters. Their peculiar form enables them to swim in water of no great depth, so that, in one or other of the species, they are very generally distributed over the coasts.

**HIPPOGLOSSUS**—the halibut—grows to a much larger size than any of the first sub-genus. It is often more than two feet in length in the British markets, and

specimens of more than double that length are not uncommon, while in the North Sea, where it is particularly abundant, it has certainly been met with eight feet long, or, as has been stated, as much as eighteen or twenty. It is a far more hardy fish, and therefore more discursive than the former ones. In some of the northern countries of Europe it is obtained in great abundance, and salted as provision against those times when, on account of the violence of the weather, the abundance of the sea cannot be got at directly. Halibut, though a thick fish, and containing a great quantity of muscle, is strong and hard, entirely destitute of the delicacy of the better species of *Platessa*, or of the richness of the turbot. Hence it is in little estimation among those who are curious in fish, and consequently sells at a moderately low price. As its range is more discursive than that of the turbot, it is much more easily caught, and there are many parts of the British shores where halibut is known as turbot, and the real turbot is termed a flounder or fluke, and sold as such. This we believe is, or at least was lately, the case in Edinburgh, in the estuary below which there is understood to be good fishing both for turbot and sole, but, either the fishing-ground is too far off, and improperly understood, or its value has been overrated, for the fishing has not hitherto succeeded. Strange stories are given of casualties that happen to large and overgrown old halibut, especially in the North Seas. It is said that their backs, which are of ample extent, become grown over with crops of sea-weed, in consequence of which they are unable to keep below the water, and thus to float sickly on the surface, until they are devoured by gulls and other aquatic birds. It is no doubt true that, owing to causes which we are not very able to explain, these fishes, as well as many other of the inhabitants of the deep, are often found floating dead on the waters, and soon become a prey to those birds whose business it is to consume the refuse of the sea; but the fact of a grove of marine vegetation upon the back of a living fish is rather too much for ordinary credulity, and puts one more in mind of a story told and credited on the banks of one of our northern rivers, where a salmon, having been speared with an instrument, the shaft of which was formed of a green sapling of mountain ash, swam down with it to the sea, and returned on its migration next autumn bearing a beautiful cluster of berries of the mountain ash on the top of the spear. The fact is, that, in endeavouring to obtain anything like good accounts of the local characters of fishes, or any other animals, in the North Seas, the people there are so remarkable for the extent of their credulity, and the singular stories which they manufacture for its gratification, that, if one trusts much to them, there is every certainty of being deceived, without any intention on their part to deceive us. It is probable that there are several varieties of halibut. The general character of all is the lateral line arched behind the pectorals; but there are some in the Mediterranean which have different characters. A small species there has the eyes on the left side of the head, and some others have been described intermediate in their form between the common halibut and the turbot; and some idea of the mass of individuals of this sub-genus caught in the North Seas, may be formed from the fact of their being sometimes caught upwards of two hundred pounds in weight.

**RHOMBUS.** The turbot sub-genus contains several species, which all have the mouth entire, the teeth numerous and slender, placed both in the jaws and on the pharynx, which characters they have in common with the halibut, but they want the spine in front of the anal fin, and the lunulated form of the tail which characterise that sub-genus. They have also the eyes on the left side of the head, and this character renders it probable that the left-headed halibut of the Mediterranean may in reality be a turbot, while some of the right headed turbots which have been described are probably halibuts.

Of all the species, the common turbot, *Rhombus maximus* (*Platessa maximus* of Linnæus), is the most celebrated. It is usually more than two feet in length, and sometimes weighs more than twenty pounds. Its general outline is between a lozenge and a circle, and having the length and breadth nearly equal. When in good condition the turbot is reckoned one of the finest of sea fishes. It is covered with small scales, and the upper and under surfaces have small tubercles upon them, which are, however, most conspicuous upon the upper side. The colour of the upper side is yellowish, clouded with brown; and that of the under side white.

The estimation in which this fish is held as an article of food makes it an object of great interest to the fishermen on many parts of the coast. It is by no means uncommon on most of the British shores, though, as it resides more in deep water than the flounders, and is more peculiar in its localities than halibut, it is not so frequently taken as it perhaps might be. It seems to be rather more abundant in our warmer seas than in our colder ones. But correct information on this point, and indeed on very many points connected with the distribution and nature of our fishing grounds, is still very much wanted. Turbot is fished for with hooks and lines, and the bait made use of is either mollusca, such as muscles or limpets, both of which make very excellent bait, or bits of herring, haddock, or of most other fishes; but the bait for turbot must be quite fresh and recent.

*Brill* (*Pleuronectes rhombus* of Linnæus) is smaller than the true turbot; has the body oval and without tubercles; and is farther distinguished from the others by having the first rays of the dorsal fin a little free, or in the form of threads at their extremities. The smooth soft skin, however, as contrasted with the rough and tuberculated one of the turbot, is however the most obvious distinguishing character. The colour above is yellowish spotted with brown, yellow, and white, while there is rarely any white on the upper part of the turbot. The flesh of the brill is inferior to that of the turbot, both in flavour and in its other qualities; but still it is very superior to that of the halibut; and though brill does not fetch anything like the price of turbot at the markets, it is still a fish which is in considerable repute. The method of capture is nearly the same with both species; but the fishing grounds differ, as brill often makes its way a considerable distance up the estuaries of the larger rivers, which is not the case with turbot.

There are two or three other species or varieties of this sub-genus, of which specimens are occasionally, though rather rarely, taken on the British coasts, especially on the south-west coasts of England and Ireland. But in attending to these rare and transient fishes, if we are to treat of fishes in a popular and economical point of view, we must be careful not to

confound the estimation in which they are held by professed and systematic naturalists with that in which they deserve to be held by the public generally. With the naturalist every animal is esteemed very much in the proportion of its rarity, so that one strange fish previously unknown is received with greater pleasure, and esteemed of more value than a whole boat load of the very best fish that was ever brought to market. This is all very well in so far as promoting the mere science of the matter is concerned; but as the end of all real science is usefulness, it were desirable that at least equal attention should be paid to that which is of the greatest value. Acting upon this conviction, we shall briefly notice those rarer species or varieties, even such of them as appear on the British coast, while we shall pass in silence those others which are equally rare in the general ichthyology of the world.

*The Whiff (R. megastoma).* This species receives its trivial name from the size of its mouth, which is large, and has the lower jaw the longest. The lateral line forms a large arch near the pectorals, and is marked by a row of tubercles along its length. The dorsal and anal fins are broadest toward the middle. The length is about a foot and a half, the colour of the upper part mottled with brown of different shades, and the under side white with a blush or tinge reddish. The eyes are large and stand up from the head, with irides of a golden yellow colour. The extremity of the tail is slightly rounded. This species has been long known upon the south coast of England, but has never occurred in such numbers as to render it a very interesting fish, in the popular sense of the term. It is more elongated in its form than most of the sub-genus.

*The Top-knot (R. punctatus).* This species is still rarer; and if those specimens which have been casually met with have been full grown ones, it is much smaller than any of the others, rarely exceeding five or six inches. Its body is rounder than that of the whiff, and the surface is rough from the scales having little projecting teeth or spines to the number of from four to eight on each scale. The colour on the upper part is black with spots of brown, and small dots of red; and that on the under side is white. It has been principally described from specimens taken from the Cornish coast; but from some of the accounts it appears to be much more common on the Shetland islands, at the opposite extremity of the British dominions. It is too rare, however, and too insignificant to be an object of general interest.

*The Scald-fish (R. arnglossus)* is a small species very local on the southern coast, so far as observation has gone. In shape it resembles the sole more than the turbot. We quote the following description of it from Mr. Hanmer. "The colour of the upper side is a pale brown or dirty white. The body has something of the same pellucid appearance as the lantern, though in a less degree. Head rather small; the jaws of equal length, blunt; the lateral line bent near the head. The dorsal fin consists of eighty-two rays, as does the anal, which reaches to the tail, the pectorals of ten rays; a double row of rays, five in each, from the ventral fins; behind is one or more short and sharp spines; the tail is rounded at the extremity; the rays of all the fins, including those of the tail, are bristly, and connected by a thin fibre or pellicle, which is easily broken. The scales are so deciduous that the friction of the trawl alone is sufficient to remove

them; when taken out of the net they are usually dead, and in that bare state, which gives some propriety to the name they are known by, of scald-fish. They seem only to be known at Plymouth, and occur there very rarely. Their length is rather more than five inches; their breadth not exceeding two inches; and are probably the smallest of the English species, and of corresponding value."

From the accounts which are given of these smaller members of the turbot sub-genus, it is probable that they run more into the character of the soles, than into that of any of the other sub-genera; and it is worthy of remark, that the sole and the turbot, which are the typical fishes of their respective divisions, are also the best in quality of all the flat-fishes; and that the sole especially is the one which is the most constantly in season.

**SOLEA.** The fishes of this division are perhaps, when we take all their qualities into account, the most valuable of the whole of the flat fish. Individually, they are not nearly so large as turbot; but when in fine condition they are perhaps more delicate; and their great abundance and long continuance in season are considerations of great importance. There are some different species or varieties of soles; but the distinctions between these are not very great; and there appears to be much similarity in the manners of the whole. They are fishes of the temperate rather than of the cold latitudes; and for this reason they are far more abundant on the southern parts of the British coasts than on the northern.

The most remarkable character of the soles is that of the mouth, which is different from the mouth of any other fish. It is twisted, or forms a curious oblique crown; and that side on which the eyes are situated has no teeth. The teeth on the other are also very small, and arranged something like the pile of velvet. Their general form is oblong; their muzzle rounded, and almost always projects beyond the mouth, the dorsal fin begins at the mouth, and both it and the anal fin are united to the caudal; thus forming a margin of fin round the whole body, with the exception of a small portion at the head end. The lateral line is straight; and the side of the head opposite to the eyes is generally villous. Their intestines are long, without cæca, but often with considerable duplications.

The species best known is the common sole; *Solea vulgaris*, which varies in length from about one foot to nearly two, and weighs from one pound to seven, though specimens of the latter weight are not very common. Its colour on the upper part is brown, and that on the under part white. The irides of the eyes are yellow, with a trace of red. On the head the lateral line is curved upwards, but it is straight in the rest of the body; the caudal fin is pointed or rounded. The scales, which are small, are rough, and fringed at their margins with about ten small spines. These scales are very beautiful in their structure, and much prized as objects for microscopic display. The skin is also strong and tough, and contains a great quantity of gelatine. The flesh when of good quality is peculiarly white and firm, and understood to be very light and easy of digestion. Soles are generally taken by a trawl net at considerable depth in the water, and at the distance of from twelve to twenty miles from the coasts. They are sought after with considerable avidity.

In the warmer seas, and in the Mediterranean

among others, there are several which are but little known on our coasts, but stray ones are occasionally met with. Of these strays, one of the most remarkable is *Solea pegasa*, which was first discovered as a British fish by Mr. Yarrell; though the fishermen in the channel have been acquainted with it for some time. The specimen described by Mr. Yarrell was eight inches in the entire length, and three inches in the greatest depth of the body, without measuring the fins. This is a much greater breadth in proportion to the length than the common sole; and the body of the fish is also more plump and fleshy, and its head blunter, shorter, and wider. The mouth is very much arched, the operculum formed externally of a single piece with a circular margin. The ground colour on the upper side a mixture of brown and yellow, with small spots of dark brown; and the tip of the pectoral fin black. There are fewer vertebrae in the spine than in the common sole, three rays fewer in the dorsal fin, one more in the pectoral, and two more in the anal, but the other fins are the same, only the tail fin is narrower in proportion. When found, this species has generally been about sixteen miles off the land, and on a bottom of clean sand. It does not appear that its flesh is inferior in quality to that of the common sole; and indeed there appears to be no great difference of any of the members of the subgenus, in whatever part of the world or locality of the sea they may be found. It seems that the sole does not get either into the strong current, or very close to the land, but rather remains on the banks when there are eddies, and deposits of matter on which it can feed; and it does not appear to rise to any great height from the bottom. Indeed from the difference in form between it and most of the others, it is probable that it is more completely a ground fish than any of them. Soles are always gregarious, or live in shoals on the same grounds; but as they are seldom, if ever, seen except when they are taken forcibly from their dwelling places by the net, we know very little of their economy or manners.

**MONOCHIRUS.** The fishes which form this subgenus, and which do not appear to have occurred on any part of the British shores even as wanderers, are soles in their general characters; and the distinction between them is chiefly in the pectoral fins, that on the same side with the eyes is very small, and the other one is either wholly wanting, or so mere a rudiment as to be barely perceptible. But as it is not easy to ascertain the precise mode and extent in which the pectoral fins of flat-fishes assist in their very singular kind of swimming, it will serve little purpose to speculate about the influence which the peculiar form of those fins in the ones now under consideration may have. The whole tribe or group are amongst the lowest dwellers in seas where observation cannot well reach them; and therefore we can say little respecting them which is not in a great measure conjectural. It is probable, however, that the quality of their flesh is superior in proportion as they have less muscular labour to perform in the search of their food; but they are truly a curious as well as a useful and valuable race.

**FLAVERIA** (Jussieu). A genus of South American herbs, one species of which is used in Chili for dying yellow. Class and order *Syngenesia segregata*, and natural order *Compositæ*.

**FLAX**, an extensive genus of annual and perennial herbs, found in many different parts of the world.

The most useful is the *Linum usitatissimum* of Linnaeus; an annual found within Britain, and much cultivated both in Scotland and Ireland, as well as in many countries in the north of Europe. A most useful oil is expressed from the seeds, and the residue called linseed cake is used as one of the most fattening kinds of food for cattle. But the filaceous substance obtained from the stalk is the staple material of the linen manufacture. Lint is the common name and is an agricultural plant. It is sowed on clean and well prepared ground in the spring, flowers in the summer, and ripens its seed in the autumn. When stripped of its capsules, the stalks are tied up in bundles and steeped in water till the woody part becomes fragile, so that it may be broken or bruised in a mill, to prepare it for the various processes of the flax dresser.

**FLAX LILY** is the *Phormium tenax* of Forster, an economical sedge-like plant, found in New Zealand. It is an hexandrious herb, and belongs to the natural order *Asphodelaceæ*. It takes its name from being employed by the inhabitants, where it grows naturally, in the manufacture of baskets, and it has been introduced into Europe as a fit plant to take the place of hemp; as the fibres obtained from its long leaves after maceration are said to be much more tenacious than any other vegetable fibre known. Whether it will be found hardy enough, for the climate of Britain is not yet ascertained, but if it could be naturalised and cultivated so far as to furnish material for the manufacture of ships' cables, it would be a valuable acquisition. The imported phormium flax has been manufactured and tested with the best hemp, and found of superior strength.

**FLAX STAR** is the *Lysimachia linum stellatum* of Linnaeus, a herbaceous annual, indigenous of Italy. It is pentandrious, and belongs to the natural order *Primulaceæ*.

**FLEA**, the ordinary generic name of a genus of small annoying insects, of which the various species attack man, and various animals and birds. See the article **PULEX**, under which name the natural history and structural peculiarities of the insects will be given.

**FLEABANE** is the *Coryza squamosa* of Linnaeus, a herbaceous biennial, native of Britain, but of no known use—not even that attributed by its name. It belongs to the natural order *Compositæ*.

**FLEMMINGIA** (Roxburgh). A genus of herbaceous and half shrubby and creeping perennials, chiefly natives of India. Class and order *Diadelphia Decandria*, and natural order *Leguminosæ*. Generic character: calyx bracteate, five-parted; standard striated; pod sitting, oval, turgid, two-valved, two-seeded; seeds globular. Several species are in our stores, and are propagated by cuttings in the usual manner. Their flowers are not very striking.

**FLINDERSIA** (R. Brown). A lofty timber tree, a native of New Holland, introduced about 1825. The flowers are decandrious, and the plants belong to *Meliaceæ*. Generic character: calyx five-cleft and persisting; petals obtuse and flat; disk surrounds the germen, cup-shaped, having ten plaits and somewhat crenated; stamens rise from the disk, alternately fertile and abortive; style simple, five-sided; stigma peltate, and five-lobed; capsule woody, spinous, five-celled, seeds winged at the apex.

There is only one species described; succeeding well with ordinary hothouse management.

**FLOSCUCULI** or cuckoo flower, is the *Lychnis flosculi* of Linnæus, a common British plant abundant in moist meadows, so called from its flowering about the same time with the arrival of the cuckoo. There is a double variety of it met with in gardens. It belongs to the natural order *Caryophyllææ*.

**FLOS JOVIS** is the *Lychnis flos Jovis* of Linnæus, a common British weed found on hedge banks and sides of roads.

**FLOWER FENCE** is the *Poinciana pulcherrima* of Linnæus, one of the most beautiful of Indian plants. It belongs to the *Leguminosæ*; and when kept in a strong heat flowers readily in our stoves. It is propagated by cuttings, but much oftener by seeds brought from its native country.

**FLOWERING ASH** is the *Ornus Europæa* of Persoon, a hardy deciduous tree, common in our arboreta, and belonging to the order *Oleinææ*.

**FLOWERING RUSH** is the *Butomus umbellatus* of Linnæus, a beautiful British plant found in pools and wet ditches.

**FLUVIALES**, an order of aquatic plants, otherwise called *Nayadacææ* or *Hydragetons*, and by some botanists *Potameææ* and *Potamopheleææ*. Like the

Fluviales.

*Lemnacææ*, these plants are believed to be destitute of spiral vessels, or if not wholly absent, they are nearly obsolete; in *Caulinia*, Amici says, no trace of them can be found. Their cellular structure likewise remains uncondensed in its outer layers; therefore no cuticular integument is formed, and they are devoid of stomata. Hence both these types descend in structure nearly to the rudimental state of the *Algææ*, from which, however, they are distinguished by their flowers, when the other diagnostics fail.

The most useful of this order is the *Zostera marina*, or grass-wrack, which forms an excellent packing for brittle ware; it is also platted into coverings for bottles and oil-flasks; and lately under the name of *Alga marina* it has been recommended for stuffing mattresses, being tolerably light and soft, and intolerant of vermin: a great recommendation in many places.

**FLY.** A name indefinitely given to all insects having gauze-like naked wings—as well as even to several kinds of beetles. Thus the *Haltica nemorum* is called the turnip-fly, and the *Elater noctilucus* fire-fly. If we would take the name in its most restricted sense, the common domestic-fly, *Musca domestica*, appears most entitled to it. See *MUSCIDÆæ*.

**FLY-CATCHER** (*Muscicapa*), a genus of birds placed by Cuvier in the first or *Dentirostral* sub-order of the great order *Passeres*, and forming the second

family of that sub-order, or the one immediately following the shrikes in structural arrangement. The birds, however, which the elder naturalists were in the habit of arranging indiscriminately as fly-catchers, are so exceedingly numerous, and differ from each other in so many points, that Cuvier has divided them into several sub-genera, of which the names are *Tyrannus*, *Muscipeta*, *Muscicapa*, *Gymnocephalus*, and *Cephalopterus*. When we come to give a more extended notice of the details, we shall be enabled to point out how those sub-genera differ from each other, while they all agree to some extent, at least in the general habit of feeding upon flies; but even here the species of some of the sub-genera are so exceedingly numerous, and the materials we are in possession of are so scanty, that it is impossible for us to enter into descriptions of them, nor if we could would it be of much utility, as the greater number are known only as museum specimens, though in their native localities most species are understood to be as abundant as the species themselves are numerous. The following is a description usually given of them by those who profess to connect the characters of birds with their external expression, and in this instance it is almost all we can obtain. They are birds which dwell in wild and solitary places, and are characteristic of wild nature, and not of the earth as cultivated by man. Their expression is accordingly sullen, and many of them have a fierce and pugnacious air. As they are obliged to seize upon their prey in mid-air, they are almost always perched upon the summit of trees, and rarely descend to the ground. As they are chasers of flies, their true country must be in the wooded regions of the globe. Accordingly, for three or four species which are known in Europe, we reckon in Africa a great number, also in the warm climates of Asia, and Australasia, and still more in America. In this last continent we find the larger species which have been denominated tyrants. As nature has increased the growth, and multiplied the number of insects in the New World, so has she opposed to them enemies more numerous and more powerful. It is a trite observation, but one which the study of nature illustrates at every step, that all in this world is balanced. When evil exists, there will always be found some equiponderating good, and it rarely happens that any one species, or genus, is suffered to multiply and extend to the serious prejudice of another. We see, it is true, everywhere a great destruction of life, but we also see an equivalent reparation; we must not take a circumscribed or conventional view of the grand operations of nature. It is impossible for any one who has not actually visited them, to form any adequate idea of the activity of life, both animal and vegetable, in those portions of the tropical countries where the powers of nature are almost unceasingly at work, or of the energy of the same powers, and the greatness of their results during the short summers of even the polar countries; and, as the productions of nature all subsist upon each other, the destroyers are always adapted to the destroyed, so that the balance of nature is kept up.

The following passage from Buffon, though perhaps not perfectly true to nature and philosophy in every respect, yet affords so lively a picture of the service which birds render in the destruction of insects, that we shall not hesitate to give it a place in our pages: "Without them," (that is the birds,) says this flowery writer, "without their assistance, vain would be the efforts of man to destroy or banish the clouds of fly-

ing insects by which he would be assailed. Innumerable in quantity, and rapid in generation, they would invade our dominions, fill the air, and devastate the earth, did not the birds restore the equilibrium of living nature, by the destruction of her superfluous products. The greatest inconvenience of warm climates is the continual torment caused there by the insect tribes. Man and the quadrupeds cannot defend themselves against them. They attack with their stings; they oppose the progress of cultivation, and devour the useful productions of the earth. They infest with their excrements or their eggs all the provisions which are necessary to be preserved. Thus we find that the beneficent birds are not even sufficiently numerous in such climates, where, nevertheless, their species are by far the most multiplied. How happens it, that in our temperate climates we are more tormented with the flies in the commencement of autumn, than in the middle of summer? Why in the fine days of October do we see the air filled with myriads of gnats? Because all the insectivorous birds such as swallows, nightingales, warblers, &c., have deserted us. This short lapse of time, during which they have too prematurely abandoned our climate, is sufficient to cause us to be more incommoded with the multitude of insects, than at any other season. What then must be the consequence, if, from the moment of their arrival—if, during the entire summer—if, in short, for the whole time of their sojournment among us, we continue to make their destruction a source of amusement?

Birds of this genus, or rather family, are found in all the warmer parts of the world; and some migrate towards the poles in the summer, and it is even said that they winter in some of the polar countries; but though this should be the case in some solitary instances, it is contrary to the usual habits of the birds, and forms no part of their general character. The more powerful ones very much resemble the shrikes both in their appearance and manners; and, though none of them are, expressly speaking, birds of prey, living principally on feathered game, yet not a few of them do occasionally prey upon little birds. The larger species of winged insects form their chief subsistence; and, as they do not prey so much upon beetles as the shrikes do, but upon flies and other insects of more lofty flight than the beetles have, they occupy a more elevated station in the forest. They are generally found perched on high stumps of trees, on the points of branches, and on other reconnoitring posts from which they can scan a considerable extent of the air; and the moment they discover an insect within the range of their vision, they dart upon it with great velocity, and generally unerring aim; seizing it with the bill after the manner of the swallow tribe. Though they do not hawk or beat the air on the wing like these, still there are many of them that approach slightly to the character of the martins, and are locally known by the same name. These usually have the tail forked, can turn in the air much more quickly than those which have the tail square or rounded; and the forked-tail ones are much more inhabitants of open places, though we believe that the greater part of the number build their nest in trees.

Most of them are migrant, or at all events discur- sive birds; and the nature of their food renders it necessary that they should be so. Some places of the tropical countries abound in insects, suited for the

nourishment of these birds at all seasons of the year; but such places are the close forests, and margins of the streams and marshes; and, wherever the ground is open, the violence of the drought sweeps away the food of such birds, and, consequently, the birds themselves are compelled to seek new pastures. But those birds are so abundant in every kind of locality, more especially in the American continent, and in some parts of Africa, that any attempt at describing their habits and localities, however meagre, would fill a large volume. We must, therefore, close our general observations, and proceed to some notice of the sub- genera, and a list of the principal species, with occa- sional short notices of a few of the more remarkable and characteristic ones.

*TYRANNUS* (*Tyrants*, or *Tyrant fly-catchers*). The species of this sub-genus are very numerous—the de- scribed ones amount to between sixty and seventy; and from the great extent of their native regions, which have not yet been explored, it is highly probable that there may be many species at present unobserved. As far as is known, they are all natives of the Ameri- can continent; and the greater number of them are found in the inter-tropical countries, though there are several which range considerably in latitude during the summer months.

The general characters are: the bill long, strong, and straight for the greater part of its length, but sud- denly hooked, or bent near the tip. The culmen or ridge is straight or rounded. They are very brave and daring birds, and do not hesitate to attack the largest birds of prey, while they are bold, and gene- rally successful in driving from their nests those birds which plunder the eggs and unfledged young. Those of the largest size not unfrequently prey upon small birds, as the shrikes do.

The *Tyrant Fly-catcher* (*Muscicapa tyrannus*), is probably one of the most characteristic species; it is found in the tropical parts of America, but ranges into the United States, and has been well described by Wilson, whose description we shall quote as being the most faithful, and at the same time one which applies in substance to several others of the species. "This," says the American ornithologist, "is the field martin of Maryland and some of the southern states, and the king bird of Pennsylvania and several of the northern districts. The epithet tyrant, which is generally applied to him by naturalists, I am not altogether so well satisfied with; some, however, may think the two terms pretty nearly synonymous.

"The trivial name king, as well as tyrant, has been bestowed on this bird for its extraordinary behaviour, and the authority it assumes over all others during the time of breeding. At that season, his extreme affection for his mate, and for his nest and young, makes him suspicious of every bird that happens to pass near his residence, so that he attacks without discrimination every intruder. In the months of May, June, and part of July, his life is one continued scene of broils and battles, in which, however, he generally comes off conqueror. Hawks and crows, the bald eagle, and the great black eagle, all equally dread a rencounter with this dauntless little cham- pion, who, as soon as he perceives one of these last approaching, launches into the air to meet him, mounts to a considerable height above him, and darts down on his back, sometimes fixing there to the great annoyance of his sovereign, who, if no convenient retreat or resting place be near, endeavours by various

evolutions to rid himself of his merciless adversary. But the king bird is not so easily dismounted. He teases the eagle incessantly, sweeps upon him from right and left, remounts that he may descend on his back with the greater violence, all the while keeping up a shrill and rapid twittering, and continuing the attack sometimes for more than a mile, till he is relieved by some other of his tribe equally eager for the contest.

"There is one bird, however, which, by its superior rapidity of flight, is sometimes more than a match for him, and I have several times witnessed his precipitate retreat before this active antagonist. This is the purple martin, one whose food and disposition is pretty similar to his own, but who has greatly the advantage of him on wing in eluding all his attacks and teasing him as he pleases. I have also seen the red-headed woodpecker, while clinging on a rail of the fence, amuse himself with the violence of the king bird, and play *bo-peep* with him round the rail, while the latter, highly irritated, made every attempt, as he swept from side to side, to strike him, but in vain. All his turbulence, however, vanishes as soon as his young are able to shift for themselves, and he is then as mild and peaceable as any other bird.

"But he has a worse habit than all these; one much more obnoxious to the husbandman, and often fatal to himself. He loves, not the honey, but the bees; and it must be confessed, is frequently on the look out for these little industrious insects. He plants himself on the post of a fence, or on a small tree in the garden, not far from the hives, and from thence sallies on them as they pass and repass, making great havoc among their numbers. His shrill twitter, so near to the house, gives intimation to the farmer of what is going on, and the gun soon closes his career for ever. Man arrogates to himself, in this case, the exclusive privilege of murder, and after putting thousands of these same little insects to death, seizes on the fruits of their labour.

"The king birds arrive in Pennsylvania about the 20th of April, sometimes in small bodies of five and six together, and are at first very silent, until they begin to pair and build their nest. This generally takes place about the first week in May. The nest is very often built in the orchard, on the horizontal branch of an apple tree; frequently also, as Catesby observes, on the sassafras tree, at no great height from the ground. The outside consists of small slender twigs, tops of withered flowers of the plant yarrow, and others well wove together with tow and wool, and is made large and remarkably firm and compact. It is usually lined with fine dry fibrous grass and horse hair. The eggs are five, of a very pale cream colour or dull white, marked with a few large spots of deep purple, and other smaller ones of light brown, chiefly, though not altogether, towards the great end. They generally build twice in the season.

"The king bird is altogether destitute of song, having only the shrill twitter above mentioned. His usual mode of flight is singular. The vibrations of his broad wings, as he moves slowly over the fields, resemble those of a hawk hovering and settling in the air to reconnoitre the ground below, and the object of the king bird is, no doubt, something similar—viz., to look out for passing insects, either in the air or among the flowers and blossoms below him. In fields of pasture he often takes his stand, on the tops

of the mullein, and other rank weeds near the cattle, and makes occasional sweeps after passing insects, particularly the large black gad-fly, so terrifying to horses and cattle. His eye moves restlessly around him, traces the flight of an insect for a moment or two, then that of a second, and even a third, until he perceives one to his liking, when, with a sweep, he pursues, seizes it, and returns to the same spot again to look out for more. This habit is so conspicuous when he is watching the bee-hive, that several intelligent farmers of my acquaintance are of opinion that he picks out only the drones, and never injures the working bees. Be this as it may, he certainly gives a preference to one bee, and one species of insect over another. He hovers over the river sometimes for a considerable time, darting after insects that frequent such places, snatching them from the surface of the water, and diving about in the air like a swallow, for he possesses at will great power of wing. Numbers of them are frequently seen thus engaged for hours together over the rivers Delaware and Schuylkill in a calm day, particularly towards evening. He bathes himself by diving repeatedly into the water from the overhanging branches of some tree, where he sits to dry and dress his plumage.

"Whatever antipathy may prevail against him for depredations on the drones, or, if you will, on the bees, I can assure the cultivator, that this bird is greatly his friend, in destroying multitudes of insects, whose larvæ prey on the harvests of his fields, particularly his corn, fruit trees, cucumbers, and pumpkins. These noxious insects are the daily food of this bird; and he destroys upon a very moderate average, some hundreds of them daily. The death of every king bird is, therefore, an actual loss to the farmer, by multiplying the numbers of destructive insects, and encouraging the depredations of crows, hawks, and eagles, who avoid as much as possible his immediate vicinity. For myself, I must say, that the king bird possesses no common share of my regard. I honour this little bird for his extreme affection for his young; for his contempt of danger, and unexampled intrepidity; for his meekness of behaviour when there are no calls on his courage, a quality which even in the human race is justly considered so noble.

"This bird is generally known from the Lakes to Florida. Besides insects, they feed, like every other species of their tribe with which I am acquainted, on various sorts of berries, particularly blackberries, of which they are extremely fond. Early in September they leave Pennsylvania on their way to the south."

This very interesting bird is about eight inches long, and one foot two inches in the expanse of the wings. The general colour on the upper part is dark bluish ash, the head and tail being nearly black; but the tip of the tail is white, and it is square at the end. The wings are brownish, with dull white margins to the quills and coverts. The general colour on the under part is pure white; but the breast is pale ash colour. The plumage on the top of the head, though not forming a regular crest, is capable of being erected; and when it is so, it displays a rich tint of flame colour; and it is from this that the bird gets its kingly name. The bill is of a black colour, very broad, and with the tip of the upper mandible descending over the under one, furnished with a lateral notch, and beset with bristles at the base. The tarsi and toes are black streaked with grey, and the irides

hazel. The female has the upper part inclining to brown, less white on the tail, and the top of the head dull orange. The young in their first plumage have no orange on the crest.

The *Great Crested Tyrant* (*T. crinatus*) is another American species found in the tropical parts, and also in the temperate. It is rather longer in the body than the former species; but less powerfully winged, and in all its character a less bold and dashing bird. The general colour on the upper part is dark greenish olive. The feathers on the head are produced and pointed, forming a loose crest, dark brown in the centre of each feather, but paler and ragged at the sides. The throat and upper part of the breast are delicate ash colour, and all the rest of the under part sulphur yellow. The wing coverts are pale fawn colour, and the primaries bright russet, marked with bands of white. The tail is of the same colour as the primaries, and slightly forked. The bill is very like that of the first mentioned species; and the tarsi and toes are bluish black. The female is very similar to the male in appearance. "The bird now before us," says Wilson, "is less generally known than the preceding, being chiefly confined to the woods. There his harsh squeak, for he has no song, is occasionally heard above most others. He also visits the orchard; is equally fond of bees; but wants the courage and magnanimity of the king bird. He arrives in Pennsylvania early in May, and builds his nest in a hollow tree deserted by the bluebird or woodpecker. The materials of which this is formed are scanty and rather novel. One of these nests, now before me, is formed of a little loose hay, feathers of the guinea fowl, hogs' bristles, pieces of cast snakes' skin, and dogs' hair. Snake skins with this bird appear to be an indispensable article, for I have never yet found one of his nests without this material forming a part of it. Whether he surrounds his nest with this by way of *terrorem*, to prevent other birds or animals from entering, or whether it be that he finds its silky softness suitable for his young, is uncertain; the fact, however, is notorious. The female lays four eggs of a dull cream colour, thickly scratched with purple lines of various tints, as if done with a pen."

The *Small Green-crested Tyrant*. This bird is also a native of America, and ranges into the United States during the summer season. It inhabits the deepest, thick shaded, solitary parts of the wood; sits generally on the lower branches; utters every minute or so a sudden sharp squeak, which is heard a considerable distance through the woods; and, as it flies from one tree to another, has a low querulous note, something like the twitterings of chickens nestling under the wings of the hen. On alighting, this sound ceases, and it utters its notes as before. It arrives from the south about the middle of May; builds on the upper side of a limb, in a low swampy part of the wood, and lays five white eggs. It leaves about the beginning of September. It is a rare and very solitary bird, always haunting the most gloomy, moist, and unfrequented parts of the forest. It feeds on flying insects, devours bees, and in the season of buckberries, they form the chief part of its food. Its northern migrations extend as far as Newfoundland. The length of this species is five inches and a half; breadth, nine inches; the upper parts are of a green olive colour, the lower pale greenish yellow, darkest on the breast; the wings deep brown, crossed with two bars of yellowish white, and a ring of the

same surrounds the eye, which is hazel. The tail is rounded at the end; the bill is remarkably flat and broad, dark brown above, and flesh colour below; legs and feet, pale ash. The female differs little from the male in colour.

Such is all the specimen we can afford to give of this exceedingly numerous genus of birds. We have taken our materials chiefly from Wilson, and these of course refer to those species which reach the United States on their summer migrations. In tropical America they are very abundant; and there are considerable diversities both in size and colour, and in the form of particular parts of the structure, especially in the termination of the tail, which is much forked in some, square over in others, and in others again rounded or wedge-shaped. These differences indicate a considerable degree of dissimilarity in some of the habits of the birds; but except as regards difference of size, and locality as being more woodland, or more a frequenter of the open places, the distinctions between them are not of very great interest; and though their history were as complete as it is imperfect, their number would preclude us from going into the details of them, therefore we must pass into the next sub-genus.

*MUSCIPETA* (*Fly-hunters*). These inhabit a different region of the world, being found only on the old continent, in Asia or Africa. There are, indeed, some species found in New Holland, but they differ from the rest in the structure of their bill. This genus is however, not very definitely arranged, the birds which are included in it differ more from each other than those of the former; and therefore it is by no means easy to determine what species ought or ought not to belong to it.

The general characters are: the bill long, and very depressed; the breadth being double the height even from the base, the culmen flat and rounded, but notwithstanding it is flexible in many species, the margins of the bill are a little curved, and there is a slight notch near the point. The base is furnished with long bristles. The feeble and flexible nature of the beak restricts them almost entirely to vegetable food, as they are unable to divide any animal or vegetable substance which has any degree of toughness or hardness. To compensate for this want of power, they are furnished, in many of the species, with floating feathers, of which those of the former sub-genus are, generally speaking, destitute. These are attached to various parts of the head, but generally speaking they consist of produced feathers in the tail, or handsome crests on the head; and in general the colours of their plumage are more rich and gay than those of the tyrants.

The greater number of those which may be regarded as the most typical, or at least as the ones upon which the sub-genus is more directly founded, are, as has been already said, natives of Africa and the south of Asia. There are, however, some species in New Holland, and some others on the American continent, which resemble the typical ones in many of their characters; but they have at the same time some which are peculiar to themselves, and therefore they should perhaps be separated as a further sub-division of this portion of the family. The New Holland ones are remarkable for the breadth and flatness of their bills; and the American ones are characterised by much greater length of the tarsi and shortness of the tail, than any of the characteristic species. We shall mention one or two of the leading ones.

*Muscipeta Paradisi*. This species has been called by various names, such as the Paradise fly-hunter, crested long tailed pie, pied bird of Paradise, and a number of others. It has a bluish-green crest on the head. The body is white; the tail wedge-shaped, with the two middle feathers much produced in the male birds, but considerably shorter in the female. The body measures about six inches in length, and the tail fourteen. It is, however, very liable to vary; for it occurs of smaller dimensions also, with most of the upper parts pale-chestnut, likewise with the breast bluish-ash. Hence it has been thrice described by Brisson under different designations; and hence the *Muscipeta Paradisi*, and the *Turdus Paradisiacus* of Gmelin, are both females of the present species. Klein mistook it for a crested thrush, Mohring for a *Monedula*, and Linné for a *Corvus*. It is a native of the Cape of Good Hope, Bengal, and Madagascar, where it haunts the mangroves, or the borders of rivers. Most of this genus, or subgenus are, indeed much more frequenters of the humid parts of warm countries than the genus *Tyrannus*, so that they are much more resident in the same locality, and live more exclusively upon insects.

The Royal Fly-hunter (*Muscipeta regia*), which has been described as the royal tody, the king of the fly catchers, and various other names, is a very handsome bird. It is brown on the upper part, and white with lines of brown on the under. The crest is spreading, and stands over the head like a parasol, the general colour brown, but the tips of the feathers black, the chin and eyelids are white, the bill brown, and the legs flesh-colour, the length of the bird is about seven inches. It is described as being one of the South American species; but it inhabits the depths of the forests and is rarely seen.

The Miller Fly-hunter (*M. pristinaria*) is a small species about the same size as the Cape tit. It is of a reddish brown colour; and inhabits southern Africa, where it gets the name of the miller, from the male making a constant clicking sound like that of the "clack" of a corn mill.

The species of these birds distributed over the richer and warmer parts of the world, are very numerous, and some of them are so rich in the tints of their colour, and so gay in their produced feathers, that they have, in many instances, been confounded with the birds of paradise, from which, however, they are quite distinct, both in their structure and their habits. They have also been not unfrequently confounded with the *todies*, from which they differ widely, as these last are syndactylic birds, having some affinity with the kingfishers, and none at all with any of the fly-catching family. Their numbers are so many however, and their history is so complicated and so imperfect, that we cannot enter further into detail.

*Platyrhynchus*, which have the bill considerably larger and broader, should perhaps be made either a separate sub-genus, or a section of the present one. The greater number of them inhabit the warmer parts of America. They are numerous, but there are few materials for any particular description of them.

Those which have the tarsi long and the tail short, inhabit nearer the ground, and use their feet much more than the others; and they in some of the species, which are not very numerous, approach to the character of the thrush.

MUSCIPETA, or the fly-catcher properly so called, has, like the rest of the family, the bill considerably

depressed, but it is not so broad in proportion, and the upper mandible has a prominent ridge on the culmen. The upper mandible is hooked at the tip, and generally much notched. There are strong hairs at the base of the bill, which partly cover the oval, basal, and lateral nostrils. The tarsus is about the same length as the middle toe, and the outer and inner toes are, generally speaking, of the same length with each other.

The species of fly-catchers, as enumerated in the books, are very many; but as it does not appear that the sub-division formed by Cuvier, has been very correctly applied to them, it is not very easy to say which, especially of the less known ones, should be taken into the list, and which excluded. Indeed the difference upon which Cuvier's sub-division is founded, is sometimes so light, and the softer billed species are so apt to have the forms of their bills altered before they are placed in Museums, that the drawing of exact lines of distinction among so many, would be no easy task. The probability is, that the true fly-catchers are all inhabitants of the eastern continent or the eastern islands, while the American ones, whatever names may be given to them, belong rather to the sub-genus tyrannus.

In Europe it is the general habit of those birds to be migratory; and though some of them range pretty far northward upon the continent, they are confined to the south east of the British islands. The reason of this is perfectly obvious, and it throws some light upon the real cause of migration in birds. The climate of Britain is warmer than that of continental countries; but the northern parts of Britain do not range into nearly so high latitudes, as those of the continent; and they contain fewer woods and marshes, and are thus less favourable to the production of insects. So striking is the difference in this respect that, while the damp forests and margins of the streams in Lapland, within the polar circle, are literally pestered with insects during the summer, to a degree little short of what prevails in the damp forests of tropical America, one may traverse the bare hills and even the banks of the streams of the north of Scotland a whole summer's day, without seeing a single fly. The account given is highly improbable, and partakes not a little of that romance and credulity which attach so much to the regions of the north; but it has been stated by authors who can be supposed to have had no intention of misleading their readers, that those birds winter as far to the north as Lapland, though there is no well authenticated account of the same species even summering in Britain as far to the northward as the most genial parts of Scotland.

There are several fly-catchers which visit Europe, and two at least which make annual excursions to the British islands. The two British species are the spotted fly-catcher *Muscipeta grisola*, and the pied fly-catcher *Muscipeta atricapilla*.

The spotted Fly-catcher. This bird arrives late in the British islands, seldom till near the month of May; and it departs generally in September. It is about six inches in length; brownish on the upper part, with a trace of red on the shoulders, a pale streak over the eye, the crown of the head spotted with darker brown, and the quills and tail feathers very dark. The under part is brownish, with dusky shafts to the feathers on the breast, and dusky spots on their webs. The bill is dusky; the sides hazel, and the

tarsi and toes, the former of which is rather short, are black. It resorts only to the rich and cultivated parts of the country, and is not found in open places or in the uplands. It is a very familiar bird, and appears to court the neighbourhood of houses, which indeed are obviously the places where its insect food is most abundant; and as it lives on winged insects and not on the caterpillars, it does not arrive so soon as those birds which feed chiefly on the latter; and it also quits the country early, because, as autumn sets in, such insects as are left, unless they are very small ones, are found near the ground; and though this bird comes near houses, its habit is to seek for its food in the free air. This food, which consists chiefly of dipterous or two winged insects, is captured as they cross the perch of the bird, so that it is a liar in wait, and springs upon its prey, instead of giving them chase upon the wing, as is the case with the fly-hunting bird. In the northern parts, it is rare; and not very abundant, except at favourite spots even in the south of England, but is very plentiful in the south of Europe. During the breeding season it frequently makes its nest in wall trees, or in the holes of old standard fruit trees, and if other circumstances do not favour it, it does not hesitate to place its nest on the ends of beams and rafters in outhouses; on these accounts it is called the beam-bird, the rafter-bird, the bee-bird, and a variety of other local names.

From their partiality to gardens and orchards, they have been regarded as destroyers of fruit. It is a prevailing notion in the county of Kent, that they suck the cherries; but individuals who have daily watched their proceedings in the French orchards, could never perceive that they attacked that fruit, though frequently allured to the trees by the presence of insects. By sudden jerks and turnings they will often lay hold on one of the latter that seemed to have eluded their pursuit; but in general they appear to be shy, melancholy, and stupid birds. Their nests, which are laboriously constructed, and which they seem to be little careful of concealing, are by no means models of neatness. The materials are generally vegetable fibres, moss, wool, &c., interwoven with spiders' webs, and lined with wool; and the situation is in trees or bushes, or the limb of a fruit tree nailed to a wall, in holes in the walls of out-buildings, or on the end of a beam, rafter, &c. The eggs are four or five in number, and not unlike those of the redbreast, being bluish white, with rust-coloured spots, but the latter more distinct, and not so much confined to the larger end, where, however, they are of a deeper tint. Both sexes share the care of incubation. When the young leave the nest, they are conducted by the parents to some neighbouring wood or grove, where insects abound, and where they may be seen darting, in every direction, in pursuit of flies. As the note of this species is a simple weak chirp, seldom uttered till the young have fled, the bird is more readily discovered than the redbreast and other summer migrants, which, perhaps, are less common. The spotted fly-catcher has been frequently noticed in Cornwall and Devonshire. A correspondent of *Loudon's Magazine of Natural History* had a nest of this bird brought to him, which he describes as follows: "It was built upon a wooden rake, that was carelessly lying on the ground in a cottage garden at Bransford, near Worcester; in this nest the female laid five eggs, and even sat on them indifferent to any one passing in the garden, till the nest was taken by a boy belonging to

the cottage. The nest is carelessly put together, yet prettily constructed of long green moss, intermixed with the catkins of the hazel, and fibres, the interior lined with thin straw and wool; eggs thickly spotted with brown."

*The Pied Fly-catcher (Muscicapa luctuosa).* This is a more handsome bird than the former, and more energetic in its manners. Its bill is of firmer struc-

Pied Fly-catcher.

ture, and it altogether approaches more near in character to the shrikes, than any of the other fly-catchers do with which we are familiar in this part of the world. An argument has been raised among naturalists whether this species be or be not a permanent inhabitant of the British islands; but it does not appear that there is much argument in favour of their residence during the winter. As summer migrants they frequent a different part of the country, keeping more inland and upland than the spotted species, and ranging along the western slope of the central elevation of England as far as Cumberland. It is worthy of remark that this bird follows nearly the same ground as the red-backed shrike, the species which, perhaps, it most resembles out of its own genus. In size it is nearly equal to the linnet; and its colours, which are subject to very remarkable seasonal changes, may be thus described, with a passing remark, that in almost all the fly-catchers with which we are well acquainted, and which are migratory, the winter plumage of the two sexes is very similar, while the summer plumage of the male bird varies much from the winter, and that of the female undergoes little or no change. The bill black, the irides of the eyes hazel, the front of the head white, the crown of the head, cheeks, eyes, and the whole of the upper parts, black, the smaller wing coverts, and the greater coverts of the primaries are dusky; the six first quill feathers, wholly dusky, the rest white at the base, increasing till the three last feathers are wholly white, except a spot of black near the point of the exterior web; the upper parts of the bird, from chin to tail, are white, the tail is dusky black, the two exterior feathers white on their outer webs, and near the shaft on the inner webs, except at the point; the legs are black. The female has no white on the forehead; the whole of the upper parts are dusky brown, the under parts are dirty white, and in the wings the white is less conspicuous than in the male.

The following facts, given by Selby, are calculated to throw considerable light upon the characters of this bird. "Its mode of life, and the species of food upon which it subsists, also militate against the idea of its wintering in this island, for, living entirely upon winged insects, it would be impossible for it to pro-

cure any adequate supply of food, during the severity of the winter season. I should even be inclined to consider the few individuals met with in England during the summer, as birds that have been driven rather out of the regular track of their polar migration; and the following fact goes far towards confirming this supposition:—In May, 1822, after a very severe storm of wind and rain from the south east, several of these birds made their appearance in Northumberland, and I procured specimens of both sexes, the males being in different states of progress towards the summer's plumage. As the weather continued cold for some days subsequent to their appearance, they were obliged to resort to dunghills, and other warm situations, for a supply of their natural food. After remaining for about a fortnight to recruit their strength (for at first they exhibited great weakness), they all disappeared; nor could I ascertain that a single pair remained in that neighbourhood during the season of incubation. Their manners, flight, and method of catching their prey, were similar to the preceding species; and they were generally mute. The West Riding of Yorkshire appears to be a district in which the Red Fly-catcher is oftener met with than in any other part of the island.—It breeds there in the holes of decayed trees, forming a nest of leaves, bark, and hay, lined with hair and feathers. The eggs are four or five in number, of a pale bluish-green colour."

This is the species called the *Beccafico* or "fig-eater" by the Italians; and in that part of Europe its flesh is held in estimation as an article of food.

The *Collared Fly-catcher* (*Muscicapa albicollis*) is even more remarkable than the last species, for the seasonal change of plumage in the male. In his winter plumage, the male is exactly like the female, namely, of a grey colour, with a white band across the wings, but his summer or nuptial plumage is very different from this. The colours are then pure black and white, very strikingly contrasted with each other; a cap on the head; the back, the wings, and the tail, are black; and the forehead, the collar, all the under part of the body, a large spot on each wing, and a small one within each external edge of the tail, is white. This is a small species, found in the dense forests of the central parts of Europe, where it nestles in the holes of trees, and is of very retired habits, and very rare, or at all events, very seldom seen. Indeed, it is probable, from the difficulty of exploring a forest, and from the fact that, within these few years, some permanently resident British kinds have been discovered, we are ignorant of many species which are in reality not rare in those places of concealment.

Such must suffice as a specimen of the true fly-catchers, for the species which inhabit Africa, Asia, and the Asiatic islands, are so very numerous that the list of their names would take up much space, and cause little information.

*Gymnocephalus* (Bald fly-catcher, or Bald tyrant). This is an American sub-genus, and has more resemblance to the tyrants than to the true fly-catchers; but there are some doubts whether it should be classed exactly in this part of the system or not. Only one species is known: it is a large bird about the size of a crow. The general colour is reddish brown with a paler tint of the same on the under part. The front and nape in the mature bird are nearly naked of feathers; but they are feathered in the young with slender grey feathers, having their points white. The bill,

though considerably compressed, is angular and much stronger than that of most of the present group. This form of the bill, with the size of the head, and its resemblance to the other members of Vieillot's genus *Coracina*, would tend to the conclusion that it is a carrion bird rather than an insect feeder. But very little is known of its habits. It is a native of the dense forests in the interior of tropical America, and has been but rarely seen in its native habitat.

*Cephalopterus* has also been placed in the genus *Coracina* by Vieillot. As is the case with the former there is only one known species of this, a native of the forests on the banks of Amazon. It is about the same size as the former, but differing from it in colour. The general plumage is black, with purple and green reflections. There is a plume of loose and floating feathers on the top of the head, which form a sort of shade or awning over the front, and are variegated with black and white. There is also a membranous production of the skin of the throat, but with feathers in branches, which hang as a sort of detached gorget. The skin, which is partially seen through these feathers, is blue; the habits are as little known as those of the former; but, from the appearance, it is probable that, like the other, it is a carrion bird, and not an insect feeder.

FLYING-FISH (*Exocoetus*), a very singular genus of soft-finned fishes, with abdominal fins; and placed by Cuvier in the pike family. They have, however, sufficient peculiarities of character to entitle them to some notice in a separate article. The most remarkable part of their structure is the great length of the pectoral fins, which are pointed, something after the form of the wings of those birds which can skim swiftly over the surface of the waters; and they are capable of being expanded by the separation of the rays, and the consequent stretching of the connecting membrane.

Their characters are: the head and body scaly, with a row of carinated scales upon each side; their head is flattened on the upper part and the sides; the dorsal fins, situated immediately over the anal, and both are considerably produced, directed backwards at both commencement and termination, straight on their margins, of nearly equal length throughout, and about equal to each other. Their ventral fins are placed in advance of the centre of gravity, broader at the extremity than the insertion, and having their extremities concave. Their eyes are large; their under jaw is the longest; both jaws have fronted teeth, and they have flattened teeth on the pharynx. They have six arches in the gills, and are furnished with air-bladders of copious size.

Though from their structure they are classed in the natural family as the pike, their characters and situation in the waters are very different from those of that voracious fish. The pike lives the tyrant of the fresh waters, capable of not only preying upon every other fish which resides in them, but sometimes assailing the aquatic birds, even the large ones, and also the mammalia which come to drink. There are no very authentic accounts of how matters stand as to mastery between the pike and the otter; but it is possible that even there, the pike may be able to keep his ground. The pike is thus a master; but, though a powerful, far from a handsome one; and in the dull and stagnant waters in which he chiefly resides, he appears to be the principal one appointed for keeping down the numbers of all the rest to the supply of food.

The flying-fishes are, on the other hand, small and feeble ; and though, at first sight, the extraordinary development of fins with which they are provided might seem to give them some certainty of escape, it rather appears that they are thereby placed in double danger. The form of their body is, no doubt, well adapted for swimming ; but it is questionable whether the great size of their fins may not, upon the whole, be an impediment to them in making their way through the waters. The form of the dorsal and anal fins must, by preventing the lateral motion of a considerable length of the body, lessen the effect of the anal fin in projecting them along. How the large pectorals may act in swimming, it is not easy to say, though they cannot, to any very great extent, produce progressive motion, and seem more likely to hinder it. At any rate the flying-fish is the constant prey of all the voracious fishes which range over the surface of the wide seas of the warm latitudes, in which only or chiefly flying fishes are found. Their power of leaping into the air, and sustaining themselves there for the space of more than half a minute, and in no instance probably exceeding, or even amounting to two hundred yards in distance, is not calculated to save them ultimately from their aquatic enemies, while it certainly exposes them to new enemies in the air ; for, when they rise in shoals, as they often do, the predatory birds, which are constantly ranging over the same seas, make prize of numbers of them ; and it is very probable that, as is the case with salmon when they leap, on being nearly overtaken by seals or porpoises, the flying-fish fall much nearer to their pursuers, than they are when they leap out of the water. Indeed, when the flying-fishes leap out of the water, it is generally observed, if the observer is near enough, that there is a shoal of coryphenes driving them along, very much in the same way that porpoises drive salmon ; and, as the exertion of the leap, and the exposure to the air, which is not their natural element, must jointly tend to weaken them : and farther, as they must require some time after their fall, before they can adjust themselves to the water, so as to have the same command of their swimming apparatus that they had when they quitted it, this must farther help to make them a more easy prey.

Though these fishes can project themselves to the height of fifteen or twenty feet above the surface of the water, and take such a direction in their leap as can carry them to a horizontal distance of a hundred and fifty or two hundred yards, it is quite a mistake to call the motion "flying," or the animals which perform it "flying-fishes." They are just as powerless in the air, and as incapable of making any effort there, as a wingless inhabitant of the land is. Their only power is in the water, and they can get no impetus of any kind but by acting against the water, as the point of resistance from which they are propelled. They are exactly in the situation of arrows shot at an oblique range. The force which urges them on acts only at the commencement ; and both the force of gravitation and the resistance of the air begin the destruction of it the instant they are in motion.

That there may be some advantages gained by the elasticity of the air reacting upon the fins and scales of a fish (and good leaping fishes are all scaly), we do not deny ; but it would be no easy problem to determine the amount or even the nature of this. It is also true that, as remarked by Cuvier, the produced and expanded pectoral fins of these fishes may prevent

their falling so rapidly as they otherwise would do. But even this acting like a parachute, and protracting of the fall, is a delivering of the fish up to an element which is not its own, and in which it is consequently quite helpless.

There is no organ that can act upon the air except a wing, and no wing can be moved but by means of pectoral muscles which have their fulcrum in a sternum of bone upon the under side of the animal. In birds the power of flight is always in proportion as the structure of skeleton supports the sternum, and in proportion as the muscles are concentrated upon this bone ; and even in those mammalia, such as the bats and a few others, which make a sort of grotesque and fluttering flight by means of an apparatus of this kind, there is always a provision bearing some resemblance to that organisation which works the wings of a bird.

In the flying-fishes, there is no such provision as this, no muscular structure by the action of which they can give their pectoral fins any motion bearing the slightest resemblance to that which wings have in flight ; the only effect of the fin being to diminish the rate and descent to the ground, in the same manner as a sheet of paper falls much more slowly, when its flat side is downward than when its edge is. The fins are, in fact, just as passive when the fish is in the air, as the sheet of paper is when it is let fall with its flat side in the position which has been stated. The arrangement of the muscles in those fishes does not differ from that of the rest of the class ; and though the fins are larger and a little different in their situations, there is not much more enlargement of bone, or provision for motion in the fins in a flying-fish than in any other. There is even less concentration of the fins in those fishes, than there is in some of the species which inhabit the bottom of the waters, and never by any chance come to the surface ; for though the ventral fins are placed farther forward than they are in many fishes, they are still abdominal fins, and not articulated to the bone of the shoulder as is the case with the ground fishes.

We are therefore to regard the flight, as it is termed, of these fishes as merely a leap, the whole exertion producing which is performed by their action on the water, and on the water alone ; and though, as is the case with any other body which is projected obliquely, they rise upward in a curve, and fall less vertically than they rise, in consequence of the wings acting as a parachute, they are just as much at the mercy of the air as any other passive substance which can be projected into it.

We have felt it necessary to state at some length the utter impossibility of these fishes being in any respect air animals, or real fliers, in consequence of the many absurdities respecting them which are found in most of the books of popular description. In these it is represented that they not only can turn to the right or left while they are in the air, but that they can ascend and descend, so as to accommodate themselves to the waving surface of the sea, and thus preserve an equal distance from the ridge and trough of the wave, as long as they are in the air. In this there is another deception which is not unworthy of notice, as illustrative of the real phenomena of the sea. The motion of the waves, though they appear to roll onward before the wind, is not a progressive motion of the water, but a mere vibration of the surface, the wave swinging on the centre of its elevation in the same manner as a pendulum swings on its point

of suspension, and following exactly the same law, so that if the total height of the wave is between 66 and 67 inches, it will vibrate seconds with the same accuracy as the pendulum of a clock; that is, each part of it will take one second to come to the level, and of course an equal time to shift from above to below, or from below to above. This motion of the surface of the water must cause a corresponding undulation of the air over the surface; and if any object whatever is simply floating in the air, and supported by that, without any exertion of its own, it must of course undulate along with it. The flying-fish is supported in this manner, and therefore when the air in which the fish is, sinks down following the trough of the sea, the fish must sink down along with it; and so also when the air is raised up by the other part of the motion, or the elevation of the ridge, that the fish must be upheaved along with it is therefore perfectly evident. There is no question that those motions of the sea, communicated to the air, and by the air to the flying-fish, which simply floats in it, may give the fish an apparently undulating, or alternately an ascending and descending motion both in its ascent and its descent to those who observe it looking endways on the waves; nor is there any doubt that this is the real cause which has led the popular describers into the blunder with regard to their ascents and their descents.

On the general subject of flying-fishes we shall take the liberty of quoting a passage from Mr. Yarrell's very scientific work on British fishes, now in the course of publication. "The most recent observations on the habits and powers of the flying-fish are those by Mr. George Bennett, the author of *Wanderings in New South Wales* and other countries, who appears to have devoted particular attention to the subject. 'I have never,' observes this gentleman, 'been able to see any percussion of the pectoral fins during flight, and the greatest length of time that I have seen these volatile fish on the fin has been thirty seconds by the watch, and their longest flight, mentioned by Captain Hall, has been two hundred yards, but he thinks that subsequent observation has extended the space. The most usual height of flight, as seen above the surface of the water, is from two to three feet; but I have known them come on board at a height of fourteen feet and upwards; and they have been well ascertained to come into the channels of a line-of-battle ship, which is considered as high as twenty feet and upwards.'

"But it must not be supposed they have the power of elevating themselves in the air, after having left their native element; for, on watching them, I have often seen them fall much below the elevation at which they first rose from the water, but never in any one instance could I observe them raise themselves from the height at which they first sprang; for I regard the elevation they take to depend on the power of the first spring or leap they make on leaving their native element.'

"The writer of the supplementary part to the class *Fishes*, in Mr. Griffith's edition of Cuvier's *Animal Kingdom*, agrees with Mr. George Bennett. He states that the flying-fishes rise into the air by thousands at once, and in all possible directions. Their flight, as it is called, carries them fifteen or eighteen feet out of the water; but it is an error to call them flying-fishes, they do not in reality fly, they only leap into the air, where they have not the power of sus-

taining themselves at will. They never come forth from the water except after a rapid course of swimming. When put alive into a vessel of sea-water, in which there was not sufficient space to acquire momentum, they were only able to rise out of it a few inches. The lines which they traverse, when they enjoy full liberty of motion, are very low curves, and always in the direction of their previous progress in the water.

"The recent observations of both these writers confirm the view taken by Cuvier of the powers of flying-fishes, as described in the *Règne Animal* of that author; who, using the words flight and wings figuratively only, says, 'their flight is never very long, and their wings (fins) only serve them as parachutes.'

"The flying-fishes themselves feed on mollusca and small fishes. Their flesh has an agreeable flavour, and is often eaten by mariners on long voyages."

We have quoted these paragraphs because they embody the testimonies of eye-witnesses, and are selected by one who is not likely to be imposed upon by fanciful theories. At the same time, we do not think any appeal to the facts necessary in this particular case, inasmuch as there is quite enough in the structure of these fishes to establish the truth of their being incapable of flight, that is, of giving themselves a new impulse from the air as a fulcrum. Some have pretended to say that they fly by means of the humidity of their pectoral fins, and fall in the water only when these become dry; but this is an absurdity which carries along with it its own refutation. That there is a certain capillary attraction between water and air is perfectly true, but the degree of this attraction is not sufficient to suspend in the air any body, however light, as may be ascertained by any one who chooses to wet any substance whatever, and commit it to the air. Its rate of falling in such a case will not be found to be materially affected by the wetting of its surface, and in the case of a substance lighter than water it will be found that the wetting makes it fall faster. There is as little truth in the notion that these fishes buoy themselves up in the air by means of any membrane connecting the fins which they extend as a sail, that is, they acquire, and can acquire no new impulse from any such contrivance, even granting that they were in possession of it. They are fairly committed to the atmosphere, in which they have not the slightest means or power of action, and thus they can remain in the atmosphere no longer than the force with which they originally project themselves from the water can sustain them.

If it were not for the peculiar form and the elongation of their fins, the flying-fishes have a good deal of similarity to the herring. They are also of a silvery lustre, and have a very brilliant appearance when a cloud of them leap simultaneously into the air. In the warm seas those displays are exceedingly common; and after ships from this country have made so much "southing" as to gain the trade wind or nearly so, these fishes and their enemies of the sea or of the air are among the most interesting phenomena of the steady and comparatively tranquil voyage. These fishes rise from the surface of the water in crowds as much thronged, and projected along with as much velocity as flocks of birds when they rise from a stubble field. But though this sight is a lively and exciting one, even it shows that they then are out of their element, or in terms of the common expression, "fish out of the water." When the flock of birds rise, they

either all rise in the same direction, or they soon acquire it; and though their motion be a horizontal spiral, or circular in the vertical direction, as it is in the flight of dotterels and some other species, they all keep course with each other. The motions of the flying-fishes are, on the other hand, perfectly irregular, and they proceed in all directions just as they happen to jerk themselves out of the water, evidently showing that when in the air they have no power in themselves, save what is derived from their simple gravitation, which at last brings them to the water upon the very same principle that it brings a stone downwards.

It would be by no means an uninteresting point in animal mechanics to find the peculiar action of the body by which those fishes raise themselves so far out of the water, and especially project themselves so far by one single exertion. We know from actual observation that salmon, trout, and other leaping fishes whose motions we can observe, leap by first curving the body to one side, and then unbending the curve by the exertion of the whole of their muscular energy; and as the body of a flying-fish is organised upon the same general principle, there is no doubt that the impulse is given to them in a similar manner, by the whole muscles being brought into vigorous play. How far the very long pectoral fins may act in elevating the fore part of the body, and how they may be assisted in this by the ventral fins, we cannot positively say; for the leap of the fishes from the water is too rapid for enabling us to observe it with so much minuteness as to be able to determine the action of the different parts. We know, however, that there are fishes which, by the action of the fins, can throw themselves to a considerable height, though this is observed chiefly in those mud fishes which leap from the oozy bottom at low water. When Captain King was surveying the north coast of New Holland, he found in some of the muddy bays, at low water, such multitudes of those jumping fishes that at first sight he imagined they were frogs; but even in the case of them, the impulse is given so suddenly that it is not easy to observe the manner in which it is performed, that is, to refer the different parts of it to the organs which more immediately produce them. In all fishes, however, the quantity of muscle bestowed on the body fins, to what part soever of the body they may be attached, is so very trifling, compared with what moves the spine and the caudal fin, that we must refer their principal action, whatever it may be, to this part of their structure; nor is there any thing in the flying-fishes which can make them an exception to this rule, there being no more accumulation of muscular substance, and consequently no more muscular strength, connected with that part of the skeleton to which they are attached, than there is connected with the same organisation of the bone in fishes which have these fins much less produced, and are incapable of projecting themselves to such heights and distances. We shall now give very brief notices of the leading species.

*Exocoetus volitans*, the common flying-fish, is the one which is most common in the warmer seas of the northern hemisphere. It is met with in the greatest numbers from about the thirtieth degree of north latitude to the equator; but it is not altogether unknown in seas much farther to the north. In the Mediterranean, which has a much more tropical character than its latitude would lead us to expect, this singular fish is by no means uncommon, and it is as much

assailed there by the coryphæa as it is in the Atlantic, though we believe that when in the air it is much more safe from the bill of the albatross. This fish, besides the singular appearance given to it, by its greatly produced fins, has a stupid look, from the disproportionate largeness of its eyes; and it is not a little remarkable that, while the shape of its body is very much that of a surface fish, such as a mackerel, a herring, or an anchovy, its organs of vision should resemble in size those of the deep water fishes, which may be supposed to have much less light in their profound abodes than is enjoyed by the flying-fish near the surface. The length of the common flying-fish varies from six inches to a foot; its ventral fins are small, and placed in a medial situation between the upper part of the gill-openings and the vent; the scales upon it are large and easily removed, and the mouth is partially extended into a sort of tube. It is said that there is a variety in the Red Sea very much resembling this one in its general appearance, which has not the habit of rising from the water; and this renders it probable that this habit is one of necessity and not of choice; that it is an attempt to escape from enemies, and not a natural exertion for the procuring of any gratification to the fish in a state of peace and safety.

This is the species of which examples have occurred on the British shores, chiefly on the south and west; and as these are interesting from the celebrity of the fish, we shall again quote Mr. Yarrell for the instances of its occurrence. "Pennant states," says Mr. Yarrell, "that in June, 1756, one was caught at a small distance from Carmarthen, in the river Towy, being brought up by the tide, which flows as far as the town. Dr. Heysham, in his Catalogue of Cumberland Animals, prefixed to Hutchinson's history of that county, says, at page 32, 'Another flying-fish was seen at Allowby in September, 1796, by Mr. Chancellor Carlyle, when he was bathing; it was near the shore and upon the surface of the water, and came within a yard of him.' According to Dr. Fleming, another occurred in July, 1823, ten miles from Bridgewater, in the Bristol Channel, a notice of which was communicated to the Linnean Society by the Rev. S. L. Jacob.

"The following letter appears in the fortieth number of the Royal Institution Journal, addressed to the editor.

"Sir—In going down Channel on the 23rd of August last, with light winds from the E. N. E., inclinable to calm, when off Portland, we were surprised by the appearance of a rather large shoal of what is commonly called the flying-fish. They were evidently closely pursued by some one of their numerous enemies, from the frequent and long flights which they took; but it was impossible to discover what that enemy was, though passing close to the vessel. The fact may possibly interest some of your numerous scientific readers.

"Sunderland, Dec. 2, 1825.

J. C. W.

"From the manuscript of Mr. Couch, another instance may be quoted of a flying-fish, 'which threw itself on shore, on the sandy margin of Helford River, near Falmouth, at full two miles from the open sea, where it was found while yet living. I was informed by Mr. John Fox, at Plymouth, in whose collection this specimen was in 1828, that it measured sixteen inches in extreme length, and that the pectoral fin was eight and a half inches long; a size which caused

me to suppose it might be the *E. evolans*, of which I possess a specimen twenty and a half inches long. There can be little doubt that this fish had been chased out of its usual haunt by some one of those voracious inhabitants of the deep by which they are continually persecuted.’”

We have given this quotation from Mr. Yarrell’s work at length, because we know that he is very particular as to his authorities; and the evidence which he has brought together renders it highly probable that more than one species of those curious fishes occasionally occur on the British shores, though so rarely and so incidentally that of course no one need directly look out for them, farther than by having their eyes about them, when they visit those parts of the coast where such fishes are most likely to be met with; and if they do this, they have a chance, indeed a certainty, of being repaid for their trouble, or rather the pleasure of using their eyes, whether they may happen to see a flying-fish or not.

As one of the distinctions of the different species of those fishes is the number of rays in the several fins, and as this is, we believe, very constant in each, we shall mention them. The present one has fourteen rays in the dorsal, fifteen to seventeen in each of the pectorals, six or seven in each of the ventrals, thirteen in the anal, and fifteen in the caudal.

*Exocetus evolans*. This species, which has been mentioned as sometimes occurring in the British seas, attains a larger size than the former, being sometimes as much as twenty inches in length. It is abundant in the Mediterranean, and when it can be captured it is excellent eating. It is also not unfrequent on the coasts of Spain. Its mouth has not the tubular form of that of the common flying-fish; its form is more nearly that of a herring, or rather of the sardine, its eyes are much smaller, and it is altogether a more handsome fish. The number of rays on its fins are thirteen or fourteen in the dorsal, thirteen in the pectorals, six in the ventrals, eleven to thirteen in the anal, and fifteen in the caudal, so that, though a larger fish, it is not so well finned, excepting in the tail, as the common flying-fish; and hence we are to conclude that though it is an equal swimmer, it is an inferior leaper.

*Exocetus exilis*. This species has not been found of exactly the same size as the last mentioned, though it has been met with larger than the common flying-fish. Its forehead is very elevated, and its ventral fins are pointed and placed nearer the tail than in the preceding species. Its anal fin is placed immediately under the dorsal, and is a little longer in the front portion than in the rear. It is represented as inhabiting both the Atlantic and the Indian Ocean, as being discursive, and found in the Red Sea, in the Mediterranean, on the coasts of Brazil, and as far north as the southern parts of the United States. The rays in its fins are ten in the dorsal, fifteen in the pectorals, six in the ventrals, eleven in the anal, and ten in the caudal.

*Exocetus mesogaster* is a species of the West Indian seas. The dorsal and anal fins have the form of a sithe-blade or falchion, which completely distinguishes it from all the others. Its ventral fins have six rays each, and its caudal twenty; those on the others have not been determined.

*Exocetus Mitchellii*. This species has been found on the American seas, and is described by Mitchell, in his account of the fishes of New York. Its head is

very like that of a herring, and the outlines of the dorsal and anal fins are nearly parallel to those of the body.

*Exocetus Nutalli* has been found in the Gulf of Mexico. Its pectoral fins are brown at the base, with two transverse bands, of which the first is forked on the outer side, and the ventral fins are marked with three brown spots. There are some other species of the division now under consideration which have been figured and described, but it is doubtful whether they may not be accidental varieties of some of those which we have noticed. All which we have hitherto alluded to have the muzzle and the lips plain, or without barbules or fibrous appendages; and we believe that most of them have been met with on both sides of Africa, though they are perhaps more abundant in the Atlantic than in the other oceans. There are a few other species, which have appendages to the mouth, and which are, we believe, so far as is known, peculiar to the American shores.

*Exocetus comatus*. This species has been observed on the shores of the United States. Its ventral fins are very long and pointed, and situated a little farther forward than in most of the others. Its anal is one half shorter than the dorsal; it has a long barbule attached to the under jaw, and the mouth is very small. The rays on the fins are, pectoral twelve, ventral six, anal six, caudal eleven.

*Exocetus furcatus*. This is found on the same shores as the former, but it is of smaller size. Its eyes are large and prominent, like those of the common flying-fish; its ventral fins, which are large, pointed, and marked with spots, are placed at the middle of the length. There is a barbule at each angle of the mouth, which extends, when stretched, as far as the base of the pectorals. This is rather a rare species, and the rays of its fins have not been counted.

*Exocetus fasciatus*. This species has been observed in the West Indian Seas, and it gets its trivial name from the brown bands or fascia which cross the pectorals. It has two long barbules on the under lip the extremities of which are divided into three branches, the middle one longer than the other two. The rays in the fins of this species are, twelve in the dorsal, ten in the anal, eighteen in the pectorals, sixteen in the ventrals, and twenty in the caudal, from which last circumstance we may be led to infer that this species is the best swimmer of the genus.

We have no doubt that, besides those which we have mentioned, there may be many species of those singular fishes; and though they are not among the most interesting inhabitants of the sea in an economical point of view, we have been induced to notice them at some length; first, because of the singularity of their habits; and secondly, because, according to many of the published accounts of them, the functions which they are said to perform are inconsistent with their structure, for a real flying-fish is as much a creature of the imagination as a flying horse.

FODIA (De Blainville). A naked mollusc, one species of which has been described, but it is so little known, that the propriety of constituting a new genus of it appears problematical.

FŒNUMGRÆCUM, is the *Trigonella fœnum-græcum*, or common fenugreek of authors, an economical plant, found wild in many places on the continent.

FŒNUS (Fabricius). A remarkable genus of hymenopterous insects, belonging to the section

*Terebrantia*, and family *Evanidiæ*, having the body long, the ovipositor long and protruded, the posterior shanks clubbed, and the fore wings with two sub-marginal cells. The abdomen, which is long and club-shaped in both sexes, is attached to the thorax close behind the scutellum, and, from its singular position, it is very much elevated in flight. The species, of which two only are found in this country (the *Sirex jaculator* of Linnæus being the type), have a good deal the appearance of ichneumons, which they also somewhat resemble in their economy, being parasites, feeding in the larva state upon other insects. They are found flying about sand banks, old walls and palings, prying into the holes and crevices with their antennæ, which, according to Bergmann, they employ for the purpose of searching for the latent grubs of certain bees, and other hymenoptera. In this respect, therefore, they seem to resemble the parasitic species of bees or sand-wasps; but it is more probable to suppose that they deposit their eggs in the bodies of the larvæ, instead of placing them at random in the cells. In the perfect state they frequent flowers, feeding upon nectar. They are often to be seen hanging upon plants by their jaws, in which position they take their repose.

FOLIACEÆ is the first class of the grand division *Cellulares*, containing the foliose and frondose ferns

Examples of the fructification of foliaceous ferns.

and their allies. It contains six orders, viz., *Filices*, *Equisetaceæ*, *Lycopodiaceæ*, *Marsileaceæ*, *Musci*, and *Hepaticæ*, described under their respective titles.

FOOL'S PARSLEY is the *Æthusa cynapium* of Linnæus. A common British weed belonging to *Umbelliferæ*.

FORMICULÆ (Linnæus)—The Ear-wig. A genus of insects serving as the type of a distinct order, named *Dermaptera* by Leach and Kirby, and *Labidowes* by Léon Dufour, but regarded by Latreille as forming a section of the order *Orthoptera*. Having given the general characters, and detailed the economy of these insects, in the article EAR-WIG, we shall here only add, that, as a group, they are technically characterised by having the tarsi three-jointed; the lower wings fan-shaped, and very much folded; the wing-covers short, square, and uniting with a straight suture; the body linear; the head not concealed by the thorax, which is shield-shaped. M. Serville has lately established numerous genera, founded upon exotic species, resting solely upon structural characters. The following are the British genera:—

*Forficula* (Linnæus). Antennæ thirteen to fifteen-jointed; tarsi with the penultimate joint bilobed; wings two. Type, *Forficula auricularia* (Linnæus).

*Chelidura* (Latreille). Antennæ twelve-jointed; tarsi with the penultimate joint bilobed; wings none. Type, *Forficula albipennis* (Charpentier).

*Labia* (Leach). Antennæ ten to twelve-jointed; tarsi simple. *Forficula minor* (Linnæus).

*Labidura* (Leach). Antennæ about twenty-five jointed; tarsi simple. *Forficula gigantea* (Fabricius).

FORMICIDÆ (Leach.) An extensive family of hymenopterous insects, belonging to the section *Aculeata*, and to the sub-section *Heterogyna* of Latreille, comprising the Linnæan genus *Formica*, or the numerous tribes of ants. Referring to the article ANT for numerous particulars of a general and popular nature relating to these insects, we shall, in the present article, give the technical characters of the family and its chief genera, and add a description of a few of the more interesting species, with such of their peculiarities of economy as may appear desirable.

In addition to the great character derived from the existence of individuals of the female sex, whose organisation has been so modified that the insects become what are termed neuters, a peculiarity dependent, as we have stated in the articles ANT and BEE, upon the social character of the insects, the *Formicidæ* are distinguished by the wingless state of their abortive females (in which respect they are different from the bees and wasps, in which the neuters are winged), by the great length of the basal joint of the antennæ in the females and neuters, in which they are elbowed at the extremity of this joint, and by the first, or the first and second, joints of the abdomen being knotted; the upper lip of the neuters is large, horny, and perpendicular, falling between the jaws; the eyes are rounded, or oval and entire; the jaws are large in many of the species, the form of these organs varying greatly in various species. In their structural characters the *Formicidæ* approach nearly to the *Tiphidæ* and *Dorylidæ*, belonging to the section of the sand-wasps. The neuters are much smaller than the males, and these are smaller than the females; the abdomen in the first and last of these sexes is composed, as in the other aculeate hymenoptera, of six segments, and that of the males of seven joints. The females and neuters are, moreover, furnished with a sting in many of the species. In those species which are destitute of a sting, the abdomen of the females is larger than that of those individuals of the same sex in other species which are provided with this instrument, but in the males it is always smaller. It is a curious circumstance, that the pupæ of those species which are furnished with a sting are inclosed in cocoons of a whitish colour, whereas the stingless species are not so inclosed. These cocoons are formed of numerous minute threads of silk, spun probably by the larva. Those species which possess a sting emit a venomous fluid into the wounds which they make, which occasions severe pain; whereas the stingless species emit a reddish transparent fluid, which they discharge upon the skin of the sufferer, causing painful pustules. This fluid, according to De Geer, is discharged from the anus; but other, and we should conceive less accurate observers, state, that it is emitted from the mouth; hence, probably, the supposition that the ants first make wounds by biting with their jaws, and then insinuate the poisonous fluid from the anus into the wound. Of the various genera into which this family has been divided by Latreille, Jurine, and others, the more remarkable are, *Formica*, *Polyergus*, *Ponera*, *Myrmica*, and *Atta*.

The genus *Formica* is distinguished by having the footstalk of the abdomen composed of a single joint the mandibles triangular and denticulated at the

edge; the females are destitute of a sting. This genus comprises about a dozen British species, the largest of which is the hill, or horse-ant, *Formica rufa* (Linneus), confounded by some with the *Formica herculeana* of the same author. The neuters in this species are about one-third of an inch long, of a black colour, with the thorax, abdominal scale, and a large part of the head, red. Unlike the *herculeana*, which builds in the trunks of trees, the *F. rufa* makes its large conical nest in the open ground, in woods, amassing together large quantities of sticks, straws, earth, &c. The number of individuals of which one of these nests is composed is very great. On disturbing the nest, they sally forth in vast quantities, assuming a most threatening aspect, and biting powerfully with their jaws, retaining hold of whatever they may seize upon with the greatest pertinacity. This species, moreover, collects grains of wheat, barley, and other small seeds, which it indiscriminately adds to the stores of vegetable matters of which its nest is formed, which circumstance doubtless gave rise to the praise bestowed upon these insects for foresight in laying up food; but if this portion of their economy has not for its object the storing of a due provision during the winter months, as has been ordinarily supposed, on account of ants lying torpid during the winter, and consequently not feeding upon such supplies, it is not the less interesting when regarded in its proper light. The nest, which at first sight appears only like a confused mass of sticks and straws, laid without order, is nevertheless ingeniously contrived to throw off the rain, to defend it from injuries of the elements, attacks of enemies, or the heat of the sun. It has generally the appearance of a rounded dome, the woody parts of the building being the most elevated; the interior of the nest, however, is much larger, and extends to a considerable depth under ground. Here innumerable avenues are constructed, and a multitude of narrower passages, placed nearly in symmetrical order circularly, and extending to the base of the dome, and which are necessary for the free ingress and egress to the workers, which, unlike those of the other species, appear to prefer the broad light of the day, not fearing to execute their labours in our sight. But there is a portion of the economy of this species which is perhaps the most interesting, because not observed in the other species, in the nests of which there is but a single entrance, and which is so placed as to prevent the ingress either of rain or of enemies. In the *Formica rufa* this is not the case; the nest has an infinity of entrances, through which, during the night, whilst the insects are all quiet within the nest, the rain might enter in torrents, or they might be surprised by their enemies. Now, this is guarded against in a singular manner. Towards sunset the nest appears in a perfect bustle, but, if attentively examined, it will be seen that all this confusion, in which the shifting of the outer materials of the nest is apparently a source of disorder, has for its object the barricading of the passages, and which is at length completely effected, the insects shutting themselves within for the night. The mere outward appearance of the nest does not convey any idea of the manner in which the entrance of water is excluded by day. This, however, is so completely effected, that, even after long rains, the interior of the nest is not even found to be damp lower than a quarter of an inch from the outer covering. Our readers will remember

the account recorded in the Bible of the tasking of the Israelites in Egypt to make bricks, and the refusal of their taskmasters to supply straw, that article being employed, when cut in pieces, for binding together the mud of which the bricks were composed. The ants pursue the same mode in the building of their nest; the particles of earth laying between the layers of straw and bits of wood being moistened by the early rains, subsequently hardened by the heat of the sun, forming a compact roof, which is again and again covered over, until the nest acquires its full size.

Another British species, *Formica sanguinea* (Latreille), is of a blood red colour, with the eyes and abdomen black, with the wings dusky at the base; the neuter is similarly coloured, except that the head is of a darker colour; and the male is black, with red legs. This species burrows in wood, and is one of those species which steals the young of other species, rearing them to perform the duties of the nest. See also POLYERGUS.

Two of the species subject to these marauders are the *Formica cucicularia* (Latreille), and *fusca* (Linneus), both of which are inhabitants of this country. The latter species is of a shining black colour, with a slight ashy tinge; its form is rather long, and it is nearly smooth; the three or four basal joints of the antennæ are of a red colour, as are also the legs; the abdominal scale is large and triangular, and the ocelli are distinct. This species establishes its nest under stones, moss, &c., and at the foot of trees, the nest being almost entirely under ground. In the nest is often to be found the larva of a *Lamellicorn* beetle, probably that of a *Cetonia*, or *Melolontha*.

Amongst the exotic species of this genus are to be found many which are extremely injurious or annoying in their habits. Of these the sugar ant of the West Indies, *Formica saccharivora* (Linneus), is perhaps the most extensively prejudicial. This species establishes its nest at the root of the sugar-canes, lime, lemon and orange-trees, where it excavates around the roots, thereby loosening the soil, so that the trees are either blown down by the violent gales in those parts of the world, or are so completely deprived of their supply of nourishment, that they soon die. Some years ago, the injuries committed by this insect were so great, that a reward of 20,000*l.* was offered by the planters to any one who should discover an effectual mode of destroying them, yet nothing could be found to stay their ravages. The aid of fire was even resorted to in vain, the insects rushing into the blaze in such myriads of millions, as to extinguish it. Vain was every attempt of man to effect their destruction, till, in 1780, it pleased Providence to annihilate them by torrents of rain.

The proceedings of another exotic species, *Formica indefessa*, of which an account has just been published by Lieutenant-Colonel W. H. Sykes, in the Transactions of the Entomological Society, exhibit one of the most extraordinary instances we have ever yet met with of the operations of that principle, or instinct, as it is called, "which enables an animal to do that which, in those things which man can do, results from a chain of reasoning, and in things which men cannot do, is not to be explained by any efforts of the intellectual faculties." The species in question was observed near Poonah, in the East Indies; and Colonel Sykes, after mentioning their fondness for saccharine matters, such as sugar-candy, preserved fruits, &c., relates the various modes by which they

succeeded in overcoming the obstacles placed in their way in order to secure those things from their attacks, swimming over the water, in which the legs of the tables were plunged, stepping, or rather jumping upon the tables, when removed to a short distance from the wall. Colonel Sykes proceeds: "The table was now removed from the wall beyond the maximum stretch of the largest ants, and I flattered myself I had triumphed over their perseverance and ingenuity, but, to my infinite surprise, in a few days the sweets teemed, as usual, with the intruders, and I was puzzled in no small degree to account for their re-appearance. Accidentally passing the table, I observed an ant upon the wall, about a foot above the level of the sweets; it fell, and, instead of passing between the wall and the table, and alighting upon the ground, the insect fell upon the table. Can it be possible, I said to myself, that this fall is designed? I stood to observe with the most intense curiosity; another ant ascended, and dropped with similar success; another and another followed; and there was no longer doubt that instinct (if instinct I must call it) had made them, in this instance, a match for reason."

The genus *Polyergus* (Latreille) is distinguished by having the antennæ placed close to the mouth; the jaws are slender and curved, the sting wanting, and the abdominal peduncle composed of a single joint. The type of this genus is the *Formica rufescens* (Latreille). This interesting species, although very common in France, has not yet been discovered in this country. At the present moment, however, a few particulars relative to the slave-trade amongst insects may not be thought uninteresting.

A, *Polyergus rufescens*. B, *Formica fusca*.

The indefatigable Huber, to whose researches upon this family of insects entomologists are so much indebted, was the first author who noticed the remarkable circumstances connected with their history. Walking in the neighbourhood of Geneva one afternoon, he observed a troop of these ants, eight or ten feet long, and three or four inches broad, crossing the path, and proceeding with rapid steps towards a nest of the *Formica fusca* above described. On arriving at its entrance, the latter (which are considerably smaller in size) attacked the strangers, but were soon put to flight, and retreated into their nest, pursued by the victors, some of whom commenced making another breach at the side of the nest, through which the remainder entered. In three or four minutes, however, the *Polyergi* returned in haste, each holding in its jaws a larva or a pupa; and, loaded in this manner, they succeeded in arriving at their own nest. On returning to look at the state of the pillaged nest, Huber found some of the black ants perched upon

the adjacent grass, each holding a larva or pupa, which it had saved from the pillage, and with which they soon returned to their nest. The next day, interested by this curious proceeding, our observer returned to the spot, and again witnessed a similar attack on another nest. Here, however, such of the victors as could not secure a larva or pupa, united in a body, and attacked a third nest, where they found an ample supply. On returning to the nest of the *Polyergus*, the surprise of M. Huber was infinitely increased at observing a number of the black ants themselves occupied upon and within the nest, and appearing to be on the most friendly terms with the *Polyergi* on their return from their marauding excursion, feeding them, and touching them with their antennæ, &c. Never, observes M. Huber, did riddle more strongly excite my curiosity than this singular discovery; and he fortunately succeeded in discovering some of the nests close to his house, so that he was able to observe them in a very satisfactory manner. He thus noticed that the black ants were engaged in repairing the nest which he had opened, digging fresh galleries, and conveying into them the stolen larvæ and pupæ; whereas the *Polyergi* took no further care about the latter, or the repairs of the nest, but retired to the deepest parts of their abode. From a long series of observations, it appeared certain that the mixed nests belong to the *Polyergi*, and that they are composed of three kinds of individuals of this species, and of workers of the *Formica fusca*, no males nor females of the latter being found in the nest; the larvæ and pupæ stolen are therefore those of neuters, which are no sooner arrived at the imago state than they share in the toils of their strange masters' nests, all of which are in fact borne by them, the *Polyergi* being unfitted for any other sort of labour but war. That this is the case, is moreover fully evident from the structure of their jaws, which are the chief organs employed in the construction of their abodes by the other ants, and which, in the *Polyergus*, instead of being large and strongly toothed, are slender, acute, and curved, and quite unfitted for carrying heavy and rough materials. That the situation of these slaves, toiling in a strange territory for strange masters, instead of labouring for their own community, cannot be regarded otherwise than as unnatural, will not be denied; but, when we reflect that these slaves have been born in this state, without knowing anything of a different state, that of freedom—that they toil not more laboriously for their masters than they would do for themselves, were they free, their instincts being essentially industrious, whether slaves or free—that they suffer no privations of food or repose—that they are even charged with the rearing of some of their own kind—and, moreover, that the state of society, dependent upon the structural peculiarities of the *Polyergus*, noticed above, requires their presence in the nest of the latter, we shall cease to think that the condition of these slaves is one of misery.

The genus *Ponera* seems intermediate between the preceding and following genera; unlike the former, the insects of which it is composed are furnished with a sting, and different from the following in having the abdominal peduncle composed of a single knot, the second joint being nearly as large as the following, from which it is, however, slightly separated at the hinder margin.

The type *Ponera contracta* (Latreille) is of a small

size ; it lives in small congregations under stones, the neuters being apparently destitute of eyes. "I have not," says Latreille, "been able distinctly to perceive the eyes, although employing a lens of half a line focus. I have seen a great number of specimens, both dead and alive, and with difficulty I have only once or twice fancied that I saw a darker coloured spot in the place of the eyes." He elsewhere adds, that "Nature having deprived this insect of one of its senses, has apportioned its operations to its powers. Hence it has not to endure the fatiguing toils of the other species, but contents itself in its little assembly, composed of a dozen individuals, with whatever it can find in the immediate vicinity of its nest." We have much pleasure in announcing the discovery of this interesting species in the neighbourhood of London.

The genus *Myrmica* is characterised by the possession of a sting, by the double knot at the base of the abdomen, by the six-jointed maxillary palpi and strong triangular mandibles. The type of the genus *Formica rubra* of Linneus (misnamed in the *Régne Animal rufa*) is one of our common British ants. It is of a red colour, with the abdomen smooth and shining, the third segment being rather darker coloured ; the first knot of the abdominal peduncles is armed beneath with a spine. This species builds its nest in the ground under stones, moss, &c. The sting of the neuters is very acute.

Another small British species, *M. unifasciata*, so named from the black belt across the pale-coloured abdomen, has lately caused considerable annoyance to the inhabitants of the houses in various parts of Brighton, as well as in the metropolis, in which its swarms have increased to such an extent, that the inhabitants have been obliged, in some instances, to quit their residences, the ants devouring or attacking every article. Mr. Spence, by whom this subject was communicated to the Entomological Society, mentioned, that the only plan hitherto discovered for their destruction was to lay down pieces of raw meat, which they assailed in great numbers, and then to throw boiling water upon them.

The only other genus which we shall here notice is that of *Atta*, which we have already mentioned in its alphabetical place, and which we again introduce for the purpose of mentioning some circumstances connected with one of the species which are doubly interesting to the naturalist ; first, from their own nature ; and, secondly, from the confirmation which they afford of a long disputed question, and the necessity which they prove to exist of scrupulously attending to every circumstance of time and place in our endeavours to reconcile the statements of ancient naturalists with the results of our own inquiries. From the days of Solomon, who said, "Go to the ant, thou sluggard, consider his ways and be wise ; which having neither captain, overseer, or ruler, prepares her bread in the summer, and gathers her food in the harvest," it has been generally considered that the storing up of food by the ant was for the purpose of ensuring against want during the winter. When, however, observers of nature began to examine the habits of our northern European species, it was soon discovered that ants lay torpid during the winter, and consequently Solomon's statement was considered to be but a figurative expression. The fact was overlooked, that in climates similar to that in which Solomon's observation was made, the winter is not

sufficiently severe to render the insects torpid ; although, by some more philosophical observers, it was suggested (Kirby and Spence, II. 46) that, in warmer regions, during the rainy season, when they are probably confined to their nests, a store of provisions may be necessary for them. These ingenious suggestions have now been proved to be perfectly correct, by the publication of Lieutenant-Colonel Sykes' account of the habits of an East Indian species of the genus *Atta* (*A. providens*, Sykes, Trans. Ent. Soc.), which lays up a store of grass-seeds (*Panicum*) in the months of January and February sufficient to last until the middle of the year. Indeed, on the 13th October, after the closing thunder storms of the monsoon, he found this species in various places employed in drying the remains of their stores which had been wetted by the rain.

**FORMICALEO.** A name given by the old writers on natural history to the insect known by the systematic name of *Myrmeleon formicarium* of Linneus, or the ant-lion. See MYRMELEONIDÆ.

**FORSKOLEA** (Linneus). A genus of annual and perennial herbs, natives of Africa, belonging to *Urticeæ*. The greenhouse species are easy of culture under the ordinary management.

**FOSSIL REMAINS.** This term is generally applied to designate the mineralised remains of organic substances, as indicating their having been dug from subterranean situations. Whenever organic remains, from their peculiar position in such situations, are preserved from decay for any considerable time, it is perfectly obvious that they must be liable to become impregnated with whatever matters may be in solution in the fluids with which they come into contact. Mineral substances may thus have been deposited in the original interstices and cavities of the organic body, without altering it in any other respect ; or in consequence of the partial removal of the original substance, may fill the space formerly occupied by it, and thus produce a cast of the same. In others the original matter appears to have undergone a decided chemical change, depending upon causes but little understood ; and one or other of these processes may have operated in producing all the varieties we find in the composition of the several earthy or metallic fossils.

The earthy substances which enter into the composition of fossils are chiefly of the argillaceous, siliceous, and calcareous kinds, in different states and proportions.

Thus we often find clay filling their cavities, and forming the beds in which they are found. They are also not unfrequent in bituminous strata, slate, and argillaceous ironstone, and a few have been met with in fullers' earth. Siliceous in different combinations enters into their composition. Quartz, chert, agate, chalcedony, jasper, flint, pitchstone, and semiopal, have all been found either forming their substance or constituting the matrix containing them. Limestone, marble, chalk, and oolite, are the most common instances of the calcareous kind. Fluete of lime has been found composing the matrix and very rarely the substance of fossils. Some nuclei have been discovered formed of hornblende, and both animal and vegetable substances have been detected in those rocks designated as basalt, wacke, and trap. Fossils are also found impregnated with metals of various kinds ; those which are the most common are iron and copper ; lead and zinc but rarely occur, and silver

still more rarely. They are generally found in the states of sulphurets or carbonates. The sulphurets and carbonates of iron are chiefly found entering into the composition of vegetable remains. Ligneous fossils of this kind exhibit the remarkable circumstance that although the texture of the wood appears unchanged, its substance has been so intersected by crystallisations that on decomposition it is resolved into an impalpable efflorescence. Those specimens of wood which have been mineralised by copper are frequently exceedingly beautiful, from the brilliant colours of the malachite which enters into their composition. Galena or sulphuret of lead has also been found in fossil wood, and blende or sulphuret of zinc, with quartz crystals investing fossil shells. Silver has been said to exist in a fossil having the appearance of ears of corn, found in the mines of Frankenberg in Hesse. Many fossils are also found either entirely unchanged, or very little altered, from their original state or condition. Shells, bones, teeth, and vegetables of various kinds, are to be met with in some alluvial deposits scarcely changed, and the remains of quadrupeds have been found well preserved in the ice of the polar circle. In limestone and other solid rocks shells are sometimes found in a nearly unaltered state. Ammonites unchanged and retaining all their pearly lustre, and resplendent tints of the most beautiful colours, are found in the splendid marble of Carinthia. Bones and shells occur in alluvial soils in a dry or fragile state, occasioned by the loss of their animal matter, this being the only change they have undergone. In fossil fishes we sometimes find not only the bones, but also the soft parts, and even the scales, more or less perfectly preserved, although a change of substance has of course taken place. Fossil vegetables occur either nearly unaltered or more or less bituminised or carbonised, in alluvial strata, in the brown coal formation, and also in some sandstones. Sometimes the organic body is merely coated or encrusted with the mineral matter, and but very slightly impregnated with it. This is most frequently the case with those found in the calc tuffa or calc sinter.

In giving a summary of fossil remains, we shall commence with the vegetable kingdom, and thence proceed with the lowest in the series of animated beings, endeavouring as briefly as possible to give an account of the most interesting objects in each division.

Vegetable remains occur in vast abundance and in great variety in different formations, particularly in the coal formation. Some of these are exceedingly well preserved, and thus afford every facility for the determination of their characters, whilst others are so much changed as to render it nearly impossible to make out the classes and orders to which they belong. In the plates of FOSSIL REMAINS in this work, representations of several impressions of fossil vegetables are given, principally ferns from the coal formation; they were copied from original subjects, and exemplify the general character of these fossils in a very striking manner. It is scarcely possible by description to succeed in an attempt to give an idea of the beauty and variety of the figures which are displayed on the surface of many of these fossils, many of which are supposed to owe their markings to the bark of different trees of antediluvian existence, and of which no trace is to be found at the present day. Some are ornamented by regularly-arranged straight ribs disposed longitudinally or transversely over their whole surface; others, by the alternate contact and

receding of gently waving lines forming areas, regularly but most singularly varying in their forms, and having, in their centres, tubercles and depressions, from which spines or bristles, in all probability, proceeded; others again exhibit surfaces apparently covered with scales, disposed in an imbricated manner, and frequently in quincunx order. Impressions of leaves occur in rocks of different descriptions, many of which resemble those of plants of the present day. In some instances beautiful specimens of aster-like flowers have been met with, and Schlotheim describes the impressions of a flower resembling a ranunculus from a metalliferous bed, near Frankenberg in Hessa; also impressions of an aquatic ranunculus or trollius in the limestone of Cenigen. Innumerable seeds, seed-vessels, &c., have been found in the blue clay of the Isle of Sheppy in the state of pyrites. Most of these belong to unknown plants, and the existing plants to which the others seem to approach are, generally speaking, those of warmer climates. They also occur in other formations, but usually in such a state as to render it almost impossible to ascertain the plant to which they belong.

The most simple of all the animal productions hitherto found in a fossil state are, the alcyonia and sponges. It has indeed been conjectured that the primitive seas may have swarmed with innumerable animals of the medusa tribe, whose bodies being entirely composed of a pulp or jelly, could not by any means have been preserved, although their decay may have had the effect of producing that peculiar fœtid odour which is emitted by some limestones. The alcyonia are most commonly found impregnated with flint. Sponges are also abundant in the fossil state, and occur in great plenty in the flint of the chalk formation, and also in the chalk itself. Very many of those habitations of Polypi, commonly called corals, are found in a fossil state, and frequently in the most beautiful state of preservation. Several genera, as the *astræa*, *madrepora*, &c., are met with in the recent and fossil state, while others, as the *cyclolites*, *turbinolia*, *favosites*, &c., occur in the fossil state alone. In some formations they are met with in the greatest abundance, particularly in that part of the oolitic strata which, from this circumstance, is called the coral rag.

Of the next class, the radiata, very numerous and beautiful specimens occur. The crinoidea abound in many strata, and although found in vast abundance are scarcely to be met with in the recent state, a circumstance which shows the exceeding difference between the animal state of the former world and the present period. Much doubt remained as to the true place of these animals, until the excellent work of the late Mr. Miller removed all doubts as to their correct situation in the system. All those remains called *entrochites* and *encrinites* by former authors belong to this class. The animals of the *asterias*, or star-fish family, from the extreme delicacy and fragile nature of their structure, speedily decay, and hence are not common in the fossil state. Of the *echini* specimens occur exhibiting very great variety of form; and these, although not met with in the older secondary rocks, are extremely abundant in the newer, particularly in the chalk. Some of the species resemble those at present met with in our seas, but none of them, as far as can be ascertained, are absolutely identical with the recent ones. In the plates of FOSSIL REMAINS figures are given of two very beautiful

*Cidaris Chaviezer.* (from the Chalk, Northfleet, Kent.)

*Cidaris Sceptifera* (from same place.)

Fish from the Chalk, Northfleet.

*Hamites Compressus.* (from the Gault, Sproughton, Yorkshire.)

Ferns from the Lower Silurian Sandstone.

Ferns from the Coal Formation.

*Belemnitica elongatus*.

specimens. They are imbedded in flint, and are particularly remarkable as exhibiting many of the spines attached, which is a circumstance of very rare occurrence.

The fossil coverings or shells of the mollusca are amongst the most abundant of the organic remains, found in the strata of which this globe is composed. They are not only of great variety of forms, but also differ considerably in magnitude. Some, as the ammonite, occur of several feet in diameter, while others are so small as to require the microscope to develop them. They are divided into univalve, those composed of one piece or valve; bivalve, those having two valves; and multivalve, those with more valves than two.

The univalves are further subdivided into unilocular, those having but one chamber, of which the common limpet is an example, and those having many chambers, called from that circumstance multilocular, which division is well exemplified by the nautilus. Of the unilocular, a vast number of genera occur in the fossil state, and many of these include numerous species. The genera of multilocular shells are not so numerous, but their internal structure is of such interest as to deserve more particular notice. We may take the nautilus as our example, as being the best known of them; this has its shell formed into a number of chambers, each separated from the other by a division which is perforated with a small hole. The inhabitant is one of the sepia or cuttle-fish tribe, and resides in the upper or last formed chamber, which is consequently the largest. A tube, which is elastic, and to which the name of siphunculus has been given, proceeds from the animal, and, passing through the perforations in the divisions and the different chambers, terminates in the first or smallest one. It is conjectured, that a portion of the shell is contained within the body of the animal, independent of the connection it has with it by means of the siphunculus, which is membranous, and it appears probable is capable of rendering the animal buoyant or otherwise at pleasure, as the air-bladder does in fishes, by its being dilatable or compressible as occasion may require. The cells or chambers appear to contain nothing but air, as the animal must leave the last one formed as it produces a new one, having no other communication than that which is kept up by means of the siphunculus. Thus the animal, as it increases in size, occupies a new chamber, which is the last in order; and in like manner all those preceding have been left empty, so that the gravity of the shell cannot be much greater than that of the water of the sea, and hence the addition of a small quantity of air by means of the siphunculus will render it buoyant, and the expulsion of the air, and possibly the addition of a small quantity of water, will cause it to sink. Of these multilocular shells some few, as the nautilus, are found living at the present time, although but rarely met with, while the fossil species are extremely numerous. From this circumstance a question has arisen as to the cause of the great disproportion between the recent and fossil shells of this family; some maintain that the genera now found fossil are absolutely extinct, while others contend that they are deep water shells, and may still exist at the bottom of the sea, far beyond the reach of our observation. The structure of these shells, however, as before explained, being so admirably and beautifully adapted to render them buoyant or the contrary at the pleasure of the animal, must be

admitted as a proof that so far from being confined of necessity at the bottom of the sea, they must (supposing them still to exist) be able occasionally to rise up to and remain for a time at the surface, and consequently would in every probability be met with; but as hitherto not a single instance of any of these extinct genera having been thus seen is recorded, we may reasonably doubt of their existence at the present time.

Of this family of shells the ammonites form a remarkable tribe, not only on account of their beauty and variety, but also for their vast abundance and wide distribution in the mineral kingdom. By the vulgar they are supposed to be petrified serpents, and by others are considered as the types of the volutes of the Ionic order. In India they are regarded with great reverence by the Hindoos, as the emblem of one of their divinities. They occur in the gault, where their colours and pearly lustre are frequently most beautifully preserved. They are exceedingly abundant in the oolite and lias; upwards of 300 species have been described.

Our limits will not allow any further details respecting the remaining members of this family. Of these the BELEMNITE has already been described under that head, one of the species of which appears in the plate of FOSSIL REMAINS; another of these curious fossils, the HAMITE, is also figured. These as well as the nummulites, orthoceralites, &c., all agree in their general character and economy with the nautilus already particularly described.

Of the bivalve fossil shells the specimens are so numerous and varied in their forms, that it would be absolutely impossible to notice them in a single article. The reader must, therefore, be referred for an account of them either to their several descriptions in this work, under their respective names, or to the numerous treatises and works on fossil conchology. The multivalves are, comparatively speaking, of but rare occurrence.

From the perishable nature of insects, animals of this class rarely occur in a fossil state. They are, however, found in considerable abundance, and in excellent preservation, in a fresh water deposit at Aix in Provence. They are there so well preserved that their genera, and even their species, may be determined; sixty-two are enumerated by M. Marcel de Serres as belonging chiefly to the orders *Diptera*, *Hemiptera*, and *Coleoptera*. Mr. Curtis observes, on reviewing a collection from Aix, that they are all of European forms, and to be referred to existing genera. But one was found to be aquatic. "The antennæ, tarsi, and trophi, are generally very obscure or distorted; in a few the claws are visible, and the sculpture and even some degree of local colouring are preserved; the nerves of the wings in almost all the diptera are perfectly distinct, and even the pubescence on the head of one of them. Several of the beetles have the wings extended beyond the elytra, as if they had made an effort to escape by flying, or had fallen into the water while on the wing."

Many species of crabs occur in a fossil state. They are found in the Stonesfield strata and in the limestone at Pappenheim. They are also extremely abundant in the blue clay of the Isle of Sheppy, and many remains of crustaceous animals also occur in the chalk. But the most singular of these crustaceous remains is a fossil which was first observed about a century ago in the Dudley limestone. It attracted

great notice by its singular form and by its being totally different from all the petrifications which had been previously seen, as well as from every organised body known to exist upon the surface of the earth. There was, however, no hesitation in referring it to the animal kingdom, but a long time elapsed before it could be determined to what class it belonged. There was no doubt, however, of their constituting a perfectly natural family, and the name *Eutomolitus* was the first proposed, which was subsequently changed into trilobites. The body of this singular fossil, as in the greater number of insects, and some crustacea, is divided transversely into three principal parts. But the most remarkable characteristic, and that which distinguishes it essentially from all known animals, is its longitudinal division into three parts or lobes by two deep furrows parallel to the axis of the body, which remarkable structure has excited the attention of all observers. At first the tails alone were noticed, and as they were considered as shells the name of *concha triloba* was given them, which designation was afterwards transferred to the whole animals by naming them trilobites, by which name they are still known. They appear to have been marine animals, their constant association in the same rocks with shells and other marine productions leaving no doubt upon this point. They must have had the power of multiplying prodigiously, certain formations being so crowded with them, as to give the appearance of their being entirely formed of their remains. They have been divided by Desmarest into five genera, each of which contains several species.

The fossil remains of fishes are found in considerable abundance. They occur under such different circumstances, in such various states, and in formations of such distant periods, as to lead the curious inquirer to expect much information of the highest interest from their examination.

In some specimens they are found nearly entire, the harder parts all in their natural situations with the scales and even the skin well preserved. In others all the other parts are removed except the skeleton, and this is more or less perfect, and frequently only the hardest parts remain, as the palates and teeth.

Fossil fishes are found in so great a variety of situations in various parts of Europe, and in formations so different, as to warrant the conjecture that they were among those animals which were of earliest creation, and whose existence has not been since interrupted. Among them are fish whose analogues live in the Indian ocean and in different seas of Africa and of North and South America. Among the fossil fish collected at Monté Bolca, there were four which were considered as corresponding to species now peculiar to the sea of Otaheité.

Vertebræ of various species of fish are extremely common, but the parts which occur most frequently in a fossil state are the teeth. They are divided into two groups, the *glossopetra* or more or less flattened teeth, which have belonged to fishes of the shark tribe, and the *bufonites*, or more or less rounded teeth, belonging to a certain species of *sparus*. The figure of a fossil fish given in the plate of fossil remains, is from a beautiful specimen found in the chalk.

Remains of the testudo or tortoise tribe have been detected in formations of different descriptions. In Great Britain they have been found in the lias near Bristol and in the oolite of Stonesfield, but the most

perfect specimens are from the clay of the Isle of Sheppy. Cuvier and others enumerate various species of land, freshwater and marine testudines found in various parts of Europe, but all of them apparently of extinct species.

Two species of crocodile have been found in the neighbourhood of Honfleur and Havre. In England they have been obtained from the Purbeck stone and from the combrash in Oxfordshire. Vertebræ have also been found in clay near Weymouth, and in the chalk in Sussex. But the most remarkable remains of amphibia are those of extinct genera of saurian animals, which differ from the crocodiles in many important particulars, and which astonish not only by their variety of form, but also by their prodigious length and dimensions. Of these the *lacerta gigantea* of Sömering, the *mososaurus* of Conybeare, is found in the soft limestone of Maestricht. The length of the skeleton is nearly twenty-four feet, the head being a sixth part of the whole length. The tail must have been exceedingly strong, and its width at the extremity must have rendered it a powerful oar, enabling the animal to resist the most agitated waters.

The *ichthyosaurus* appears to have been a marine oviparous animal, closely agreeing in the whole osteology of the head and sternum with the saurian tribe, except that the bones approximate to those of fishes in various particulars—whence the name indicative of its being the fish-like lizard is derived. The extremities terminate in four swimming paws or paddles, composed of a series of flat polygonal bones. Several species occur, found chiefly in the lias limestone of England.

The *plesiosaurus* is another of these singular fossil animals. It appears from its structure to have formed an intermediate link between the crocodile and the *ichthyosaurus*. But what chiefly distinguishes this animal is the prodigious length of its neck, by which it must have been enabled to seize its prey when at a considerable distance. This also occurs imbedded in the lias limestone in England. Magnificent plates of these last two genera have been published by Hawkins, in his work on the *ichthyosauri* and the *plesiosauri*, the originals of which are now deposited in the British Museum, forming without doubt, the most splendid collection of the fossil remains of these animals in existence. Various other genera have been noticed, of these the *iguanodon*, a reptile of enormous size, has been well illustrated by Mr. Mantell, by whom it was discovered in the strata of Tilgate forest in Sussex.

There is a remarkable genus of fossil flying animals about which considerable obscurity exists as to its proper place in the system. Blumenbach considered it as a bird, while Cuvier referred it to the amphibia. This is the *pterodactyle* or flying lizard. The skull of this singular creature must have been very large in proportion to the size of the skeleton, the jaws themselves being longer than the body, and furnished with sharp slightly incurvated teeth. The orbits of the eyes are exceedingly large, and hence it is probable that it was a nocturnal animal, like the bat, which it also at first sight very much resembles in the wings and other particulars.

The remains of birds are of rare occurrence in a fossil state, and the few specimens yet found afford results far less satisfactory than those obtained by the study of the fossil bones of other animals. Species

referred to the following genera are enumerated as found in the gypsum and limestone of the Paris formations, owl, buzzard, starling, ibis, quail, tern, curlew and pelican.

Among the most extraordinary fossil remains of the class mammalia, we must mention those of the extinct genera of the sloth kind. These, although not numerous, deserve notice on account of their magnitude and singular organisation. Two species have been described: the megatherium, properly so called, and the megalonyx. Of the first of these a complete skeleton was found in diluvial soil near Buenos Ayres, and sent to Madrid, where it was set up. It is fourteen feet long, and seven Spanish feet in height. The skeleton is so exceedingly rude and unshapely, that the clumsy skeletons of the elephant and hippopotamus when placed beside it would appear quite slender and light. Some of the bones of this extinct monster are in the museum of the College of Surgeons—casts of which have been taken and set up in the British Museum, where they excite great attention. It is one of the largest and most massive of the fossil quadrupeds hitherto discovered. Judging from its structure it must have been exceedingly slow and dragging in its motions; and, with the exception of its enormous claws, it appears to have been more defenceless than any of the other large animals. The form of its teeth prove it to have lived upon vegetables, and its huge claws were possibly used for digging up the roots upon which it is supposed to have fed. The megalonyx agrees in its general form and structure with the megatherium, and also resembles it in other respects. It has been found only in limestone caverns in Virginia.

The fossil remains of the elephant or mammoth, as it is commonly called, are found in vast abundance. Single bones, teeth, and even perfect skeletons occur, and one instance is on record of the whole animal being found in a perfect state imbedded in ice. The circumstances of this fact are so extraordinary as to merit a more detailed account. In the year 1799, a Tongoose fisherman observed on the borders of the Icy Sea near the mouth of the Neva, in the midst of fragments of ice, a shapeless mass, the nature of which he could not conjecture. Every succeeding year it became more developed, until at length it fell out of the ice upon a bank of sand. The fisherman possessed himself of the tusks, which he sold. Two years after one of the associates of the academy, of St. Petersburg was informed of this discovery and immediately repaired to the spot. He found the animal already greatly mutilated. The flesh had been partly cut away by the Yakoots for their dogs, and some of it had been devoured by wild beasts; still, however, the skeleton was entire, with the exception of one of the fore legs. The head was covered with a hard skin. One of the ears, in high preservation, was furnished with a tuft of hair, and the pupil of the eye was discernible. The skin was covered with black hair and an under coat of wool of a reddish yellow colour. The neck was furnished with a long mane. There were stiff black bristles from twelve to fifteen inches long, which belonged to the mane, tail, and ears. The remains were so heavy that ten persons had much difficulty in removing them. More than thirty pounds weight of hairs and bristles were carried away. The tusks were more than nine feet long. The remains of this singular and valuable relic of a former world were collected with

the utmost care, and are at present in the possession of the Emperor of Russia. From the wool which was found next the skin of this animal, Cuvier thinks it probable that the northern fossil elephants were inhabitants of those cold countries where their remains are found. The discovery of this body in so perfect a state also proves another important point, namely, that these animals must have been arrested by the ice immediately after their death, and consequently could not have floated there from distant southern regions. These remains are found in the greatest abundance in Siberia; and one of the islands to the north of that country abounds so much in these and other fossil bones, that the whole island is described as appearing to be entirely composed of them. This is doubtless an exaggeration, but it serves to show the wonderful abundance of these fossil remains.

The remarkable fossil genus mastodon is chiefly confined to North America. From a nearly complete skeleton discovered and set up by Mr. Wilson Neale, of Philadelphia, we learn that the species called the great mastodon of the Ohio was about as tall as an elephant, but with longer and thicker limbs. It was probably provided with a proboscis, or trunk, and had tusks similar to those of the elephant. In one of the dépôts of these remains in Virginia, was found, inclosed with bones, a mass of roots, little branches, grass, and leaves, in a half bruised state, the whole enveloped in a kind of sac, which was considered to be the stomach of the animal. From this it appears to have lived on roots and the fleshy parts of plants, and hence this kind of food attracted it to soft marshy places, where its fossil remains are chiefly found. It is more common in North America than in any other part of the world, although its remains have also been found in Siberia. Another species, rather smaller, is described, which is found in Europe, and also in North America. Remains of several other species are also said to exist.

The fossil *Pachydermata* discovered by Cuvier in the plaster quarries of Paris, are also of the highest interest. In the *Anoplotheria* and *Palæotheria* we are presented with a view of an animal population of a former period of the earth's existence, which has been totally destroyed. Wherever these remains have been discovered, there are vast superincumbent beds of marine formation; proving the invasion and long continuance of the sea in the countries inhabited by those races.

The bones also which have been found in caverns in Germany, England, &c., although belonging to a far more recent period, deserve attention. In the cavern at Kirkdale, in Yorkshire, Dr. Buckland found bones of the hyena, tiger, bear, wolf, fox, weasel, elephant, horse, rhinoceros, hippopotamus, ox, deer, hare, rabbit, water rat, mouse, and others which were considered as belonging to various birds. In the German caverns at Gailereuth, &c., we meet with two extinct species of bear, hyæna, fox, polecat, and wolf. These remains are embedded in a sedimentary deposit, which is usually covered with a stalagmitic crust. They occur in such abundance as in many places to be used for manuring the adjacent lands. The animals to which these bones belonged decidedly constituted the population which occupied our part of the world, at the era of the last great catastrophe which destroyed their races, and prepared the soil on which animals of our own era exist. Whatever resemblances certain of their species may present to those of our own times

it is no less remarkable than certain, that their general character was very different, and that most of their races have been entirely annihilated.

The species of deer known by the name of the Irish elk, affords one instance, at least, of an animal which has apparently become extinct since the existence of man upon the earth. It occurs in a fossil state in Ireland, the Isle of Man, England, Germany, and France. The most perfect specimen of the skeleton of this species hitherto met with, is that which was found in the Isle of Man, and is now preserved in the Museum of the University of Edinburgh. It is six feet high, nine feet long, and in height, to the tip of the right horn, nine feet seven and a half inches. It was embedded in a loose shell marl, in which were numerous embedded roots and branches; over the marl was a bed of sand, above this a bed of peat, and over the peat the common soil of the country.

Hitherto no remains of apes, baboons, monkeys, or other tribes of the order *Quadrumanæ*, have been met with, nor any trace of their existence, unless we consider that those extraordinary casts in sandstone of the impressions of the feet of some unknown animal, which have been found in Germany, are to be referred to animals of this kind. A slab of this stone, with these impressions, is in the British Museum, and the cast taken from it exhibits the appearance of the impression of a large thumb, with indistinct traces of parts of the other extremities of some animal, occurring at regular distances, forming an object well worth the attention of the curious visitor.

A fact must now be noticed connected with fossil osteology, of the most remarkable and striking kind. We find the remains of different genera of quadrupeds, birds, reptiles, fishes, insects, mollusca, and vegetables, in the fossil state; but hitherto no human remains have been found, nor any traces of the works of man in those particular formations in which these different organic fossils have been discovered; that is to say, no human bones have been found in the regular strata of the surface of the globe. In alluvial beds, peat bogs, and ancient burial grounds, they are dug up as abundantly as the bones of any other living species; but not a fragment of human bone has been found in such situations as to lead us to suppose that man was contemporary with the more ancient races, with the *Paleotheria*, *Anoplotheria*, or even with the elephants, megatheria, and rhinoceroses of a comparatively recent era. Nothing has been found to indicate the existence of the human race at a period antecedent to the last general catastrophe of the globe, at least, in those parts where the study of organic remains has been followed up by a careful examination of the strata. It is true that several years ago human skeletons were discovered in a compact calcareous rock in the island of Guadaloupe. A mass of this rock, containing a pretty well preserved human skeleton, but without the head, has been deposited in the British museum. The rock, on examination, proved to be a mere alluvial mass, formed of pieces of coral, that appears to have been thrown up on shore by the sea, and afterwards cemented together by water impregnated with calcareous matter. This, therefore, can be no proof of the ancient existence of man, and the writer of this article considers himself justified in concluding that the human race was not coeval with the fossil genera and species.

The study of fossil remains is one of the utmost importance in geology. By it alone we are enabled

to form precise notions concerning the history of the earth. Had these been totally neglected, we could never have imagined that successive eras, and a series of different operations had taken place in the formation of the globe. By them alone we are assured that the covering of this planet has not always been the same, as it is obvious that before they were buried in its depths they must have existed at the surface. By them we learn that certain strata have been tranquilly deposited in a fluid mass; that the variations in the strata have corresponded with those of the fluid; that the translation of this fluid occasioned their denudation, and that this denudation has taken place more than once. Nothing of this could have been ascertained with any degree of certainty, but for the study of fossil organic remains.

**FOSSORES** (Latreille). An extensive sub-section of hymenopterous insects belonging to the division *Aculeata*, or those furnished with a sting in the females. There are only two kinds of individuals in each species, male and female, both of which are winged. They are solitary in their habits, each species taking upon itself the care of forming and provisioning, or, at least, seeking a nest for its progeny. The legs are formed only for walking or for burrowing; the wings are never folded longitudinally as in the wasps. In our article **ENTOMOLOGY** we have figured the fore leg of one of the burrowing species of this sub-division, by means of which the females are enabled to excavate cells in the ground or in wood, in which they then bury a certain quantity of other insects, spiders, or larvæ, which they have half stung to death, which serve for the food of the larvæ hatched from the eggs deposited in the cells at the same time. These larvæ are footless grubs of a fleshy consistence, resembling a short worm or maggot: when arrived at the full size they spin a silken cocoon, in which they are transformed to pupæ: the perfect insect is generally extremely active, feeding upon the nectar of flowers. Some of the exotic species are of very large size, and their stings are very painful. Some of the species belonging to the sub-division are not provided with organs for burrowing, and accordingly are compelled, like the parasite bees, to deposit their eggs in the already provisioned nests of other species. M. le Comte de Saint Fargeau was the first author who noticed this parasitic connexion between the species; but by raising a theory upon too limited observations, he considered that all the species whose legs were destitute of the brush-like spines, were necessarily parasitic. This theory was successfully attacked by Mr. Shuckard, in the first number of the *Transactions of the Entomological Society*, by whom it was shown that amongst the species destitute of spines, many were wood-borers; hence he proposed the theory that those species, and those only, which burrow in sand are furnished with spines; subsequent observations have, however, convinced the writer of this article that Mr. Shuckard has likewise founded his theory upon too limited observation, several spineless species having been detected in burrowing in sand.

This sub-section comprises the families *Scolidæ*, *Sapygidæ*, *Sphegidae*, *Bembicidæ*, *Larvidæ*, *Nyssonidæ*, and *Crabronidæ* (including the *Cercerides*). To these groups the *Mutillidæ* must evidently be added, which differ only in the apterous condition of the females.

**FOTHERGILLIA** (Linnæus). A genus of North

American deciduous shrubs long introduced into our gardens. Class and order *Polyandria Digynia*, and natural order *Hamamelidaceæ*. Generic character: calyx bell-shaped, truncated, whole, persisting; corolla none; stamens filaments thickened above; anthers erect, quadrangular, and two-celled; styles two, awl-like; stigma simple; capsule hard, two-celled, cells two-valved; seeds single and bony. These ornamental plants thrive in the borders of moor earth, and are increased by layers.

**FOX** (*Vulpes*). A genus of mammalia belonging to the sub-order or section *Carnivora* of Cuvier's great order *Carnassier* in the Animal Kingdom. They are usually considered as only a variety of the extensive genus *Canis* (dog), which, in the systems, comprises the dogs properly so called, and along with them the wolves, and the jackals, all considered as dogs; and also the foxes, and the fenne, together with the wild dog of the Cape, which last has in fact many of the characters of the hyenas, though its teeth are said to be differently constructed.

Generally speaking, foxes do not differ much in their organisation from dogs. Like these, they have six incisive teeth in each jaw; one canine on each side of both, six cheek teeth above and seven below in each side; the first four in the lower jaw and first three in the upper small, but with trenchant edges. The great carnivorous bruising teeth, situated behind the trenchant ones, with two points and a tubercle on the inside in the upper jaw; but the lower jaw with the last lobe of each entirely tubercular. The last two teeth in both sides of each jaw wholly tubercular on their upper surfaces, and thus indicating that the animals are not in the highest degree carnivorous, but can subsist upon other aliment besides flesh. The foxes have also, like the dogs, five toes on the fore feet, and four on the hind; and the females have mammae both on the belly and in the groin.

The distinguishing characters of the foxes from the dogs, and from all the other sections of the genus, are: the pupils of the eyes closing on a vertical line, though opening nearly to a circle; the tail longer and much more bushy or thickly covered with fur; the skin altogether covered with finer and closer fur, in some of the varieties of great beauty and esteemed at a high price; and the muzzle more elongated and pointed at least than any of the others in a wild state. The incisive teeth in the upper jaw are also more furrowed; they all have a foetid and offensive, though peculiar, smell, and they burrow more habitually in the earth. Perhaps we may add that their canine teeth are more keenly pointed, that those in the lower jaw are larger in proportion to those in the upper, that they are more advanced in the jaw, and stand more apart from each other at the points. From this structure of the most efficient part of the mouth in killing their prey, it follows almost by necessary consequence that the foxes inflict a mortal wound by a single bite, and do not mangle their prey like some of the others. The smallness of the muzzle, the nearness of the deadly weapons to its point, the length of the jaws, and the consequent velocity with which the large and keenly-pointed canines in the lower jaw can be moved, enable them to reach the vulnerable part of their prey more readily, and inflict their wound more speedily and certainly.

It is in their manners, however, that the foxes are most distinguished from all other canine animals. Many of the others are nocturnal as well as the foxes,

but none of them have that form of nocturnal eye which enables the owner to see prey when above it; and thus the eyes alone of the foxes would point out their great propensity to robbing a hen roost, or seizing pheasants and other gallinaceous birds on their perches, when perching near the ground. Foxes are also more decidedly dwellers in holes of their own excavation, or "earths," as they are technically called, than any others of the family, though the whole do reside in dens and hiding places, except when they are abroad hunting. The structure and formation of the eye, which we have noticed, and also this mode of lodging, indicate, if not a cowardly, at least a cautious animal, which will not attack any creature that may stand on the defensive. The softness of the fur too and the bushiness of the tail all indicate a capacity of proceeding silently through brakes and bushes, so as to come upon the prey unawares, and kill it by the rapid snapping bite, before it is aroused either for escape or for defence. Another character which, among the whole race, is peculiar to the foxes, is that of being quite solitary in their operations, and never joining for any common purpose where numbers can make up for the want of individual strength. We know little of dogs in a state of nature, as may be seen by referring to the article Dog in this Cyclopædia; but it is probable that in this state they invariably help one another in cases of need. This is the known practice both of the wolf and the jackal, the first of which sometimes make attacks in very formidable troops, and the latter, though not so bold and ferocious, are generally found yelping and prowling for their food in company with each other. But it does not appear that the barking of foxes is ever to be viewed in the light of an assembling call. In the season, it may be calling and answering between mate and mate, and at other times it may be done with the intention of alarming the prey, and causing it to make so much noise that the acute ear of the fox may hear it in the dark and steal upon it. There seems to be in this habit enough to entitle foxes to separate consideration as a subgenus, if not a separate genus from all the rest; because it indicates that foxes act a part in the economy of nature which could not be exactly supplied by any or even by all the rest of the race, if the foxes should become extinct.

This, if we could arrive at it with knowledge sufficiently minute and accurate, is perhaps the real ground upon which the distinctions of genera should be placed; because the part which it plays in nature is the ground upon which to estimate the real value of any animal; and if this could be made the foundation of our systems of classing, then those systems would have some better claims to the merit of being natural than they have even when they are arranged most strictly according to the anatomical structure, both external and internal. That there is much in the organisation we do not deny; but still organisation is not life, and therefore when we have studied that even to the utmost, there is still something in the animal which is not exhausted, but which claims our inquiry, and is in all probability more fitted for rewarding it than even the other.

Foxes are found in many parts of the world; but they are most abundant in temperate and cold climates, especially the latter; so that there are probably more foxes in the cold parts of the northern latitudes of both continents than there are in all the rest of the world taken together. The character of their cover-

ing indeed points them out as animals fitted to endure the rigours of climate; and their habits conspire with their covering in enabling them to do this. They are always in cover of some kind, unless when they can with safety to themselves, and also with "chance" of prey, prowl about so as to keep themselves in heat. In the north they are indeed found in great numbers, and are obliged to be abroad at times when the weather is severe; but in these places and at these seasons, their coats are proof against all weathers, and while the temperature remains so low that there is no chance of thawing, a burrow in the snow is as snug and warm as a burrow in the earth.

Foxes are not migrant in any country, and they do not shift their quarters much with the seasons, even in those places where there is a shifting of this kind on the part of other animals. When the winter is severe the wolves descend in numbers from the mountain forests, and often commit fearful devastation; but foxes do not even invade hen-roosts more in the winter than in the warm season, if they even do it as much.

This constant remaining in the same locality through the vicissitudes of the year, and being tempered in their covering to the change, is in all probability one of the reasons why there is so much difference of opinion about the varieties or species of them. Amid all the apparent variety, they are, however, true to the habit; and in this respect there is perhaps less variation among foxes than among any other animals which are equally numerous and widely spread.

With all their powers of change, they appear, however, to be hardy and healthy animals, and we believe the body of a fox that has died a natural death is a very rare occurrence. No doubt there is, on the part of mankind, a strong propensity to thin their numbers, for mere sport, for the sake of the skin, and from the havoc which they commit on the weaker sorts of domestic animals, birds especially, and game. There is one point connected with them which is worthy of some attention: they do not fade before the progress of cultivation, as many predatory animals fade; and, therefore, it would be worth while to ascertain whether, in spite of his mischief in the poultry yard, reynard be not a useful animal.

Common as foxes are, and much as they have occupied the attention and drawn down upon themselves the vengeance of mankind, there are very considerable doubts respecting some of the species. This is especially the case with those foxes which inhabit the polar climates of the northern hemisphere; and indeed it is there that we might be prepared to expect the greatest confusion on the part of those who establish a different species upon mere diversity in size or colour. We shall notice what we consider as imaginary species in our list of those to which they appear really to belong; and thus restricted, the list will not exceed six or seven species. We begin with the common fox, so well known in our own country.

**THE COMMON FOX** (*Vulpes vulgaris*). The medium height of the common fox is about one foot. From muzzle to the other extremity of the body it averages about two feet and a half. A fawn colour intermixed with black and white constitutes its characteristic hue. On the head, along the spinal column, the flanks, the posterior part of the limbs, and the sides of the tail, the fawn predominates. Greyish fawn sprinkled with white prevails on the thighs and shoulders. The under part of the neck and breast anteriorly, a kind of half collar

at the bottom of the neck, and a narrow spot commencing at the internal angle of the eye, and descending towards the throat, are black. It is quite unnecessary, however, to dilate on the colours of an animal so well known. The coat is thick, especially on the back and tail. In winter the woolly are more abundant than the silky, and the fur is more valuable at that season. The silky hairs predominate in summer, and their number is not so great. The physiognomy of the common fox, its slender muzzle, large head, and shortness of limbs in comparison of the body, are very generally known. The organisation of the fox and dog, with one exception, are precisely similar. This exception is the eye, which in the fox resembles that of our domestic cat, and not that of the dog. In a strong light the pupil contracts, and appears only a narrow and longitudinal section. It opens and assumes a circular form only during twilight or night. Consequently this animal, like the cat, avoids the light, and prefers darkness and obscurity.

We need scarcely mention that the fox has been proverbially celebrated for his cunning, and although this feature in his character has given rise to much exaggeration and fable, his proceedings are more under the guidance of subtlety and craft than of courage, or the spirit of enterprise. He chooses his habitation in brakes, woods, or coppices, preparing his bed under hard ground, the roots of trees, or similar situations, where he can contrive proper outlets to escape from danger. He does not always take the trouble of making a hole for himself, but often procures accommodation by dispossessing the badger. His lodge is seldom remote from the habitations of man, and is frequently found in the neighbourhood of some farm-yard or village. He listens to the crowing of the cocks, and the cries of the poultry, scents them at a distance, selects his time with judgment, conceals his road as well as his purpose, slips forward with caution, sometimes even trailing his body, and very seldom makes a fruitless expedition. If he can either leap over the wall, or creep in underneath, he ravages the court-yard, puts all to death, and retires softly with his prey, which he conceals under herbage, or carries off to his kennel. In a short time he returns for more, which he bears away, or conceals in the same manner, but in a different place. In this way he proceeds systematically, till the progress of the sun, or some movement perceived in the house, warns him that it is time to suspend his operations, and to retire to his den. The nets and bird-lime of the fowler he visits early in the morning, removing, in succession, the birds that happen to be entangled, hiding them in different places, where he perfectly well knows where to find them, even after some days have elapsed. The young hares are hunted by him in the plains, he seizes old ones in their forms; digs out rabbits from their warren; detects the nests of partridges and quails, seizes the mother birds whilst sitting on their eggs, and destroys a vast quantity of game. In procuring young rabbits from their burrows, he follows their scent above ground, till he comes to the end where they lie, and then, scratching up the earth, descends on them and despatches them. Should there be no other victims, he makes war on rats, field-mice, serpents, lizards, toads, and moles, of which he consumes great numbers, playing with them, like the cat, before devouring them. He will also eat roots and insects when urged by hunger, and will seize on crabs, shrimps, and shell-fish, when near

the sea-coast. Grapes, and other sweet fruits, he manifests a predilection for, and will boldly attack wild bees to get at their stores. When assailed by the hosts which fasten on him with their stings, he retires, but only for a few minutes, rids himself of his opponents by rolling on the ground, and crushing all that stick to him, and then returns to the charge, and devours both honey and wax.

The active foresight of the fox will often prompt him, even when sated with food, to prolong his researches, less with the intention of discovering fresh booty than of exploring the details of his future resources. Thus he frequently returns to the various holes which he has cleared, surveys them with much precaution, enters into them, and slyly examines their different issues. He approaches objects that are new to him with cautious slowness, and which, on account of their novelty, excite his suspicion and distrust. This timid prudence, however, completely disappears in the female fox when she has young ones to nurse and defend. The maternal instinct which, in all species, the human not excepted, is probably the strongest of all feelings, effaces the specific character of the animal. There is no sentiment so completely disinterested as this, none in which the sacrifice of self is so instantaneous and so complete. The mother will not hesitate a moment to endure the utmost privation, to brave the most appalling danger, nay, to encounter the certainty of death, for the preservation of her infant offspring. She that, but a little before, was all gentleness, shrinking timidity, and fastidious delicacy, who could not bear the winds of Heaven to visit her face too roughly, on the sudden becomes bold, fierce, and resolute, unshaken by all that is trying, and unrevolted by all that is disgusting. The female fox watches incessantly over her young, provides for all their wants with unwearied assiduity, and exhibits an audacity very foreign to her general disposition against their most formidable adversaries.

We should be inclined to trace this maternal instinct, if we might presume to conjecture at the proximate cause of it, like many other powerful sentiments in animal nature, to some sensation of physical pleasure by which its exercise is accompanied. Those feelings, even in man, which assume for a time the completest domination over his constitution, have sensual pleasure as their origin and object, however remote their apparent distance from such a source may be, however they may be glossed over by high-sounding names, or to whatever degree of refinement they may be spun by those mighty casuists, vanity and self-love. Most of our feelings and ideas, however refined and abstracted, are resolvable, in their last analysis, into physical sensation, and the closer their connexion is with this primal source, the more impetuous and commanding is their influence. If this be the case with man, it is much more strikingly so with the brute creation.

Foxes are generally in heat about the month of February. They are then heard to utter very sharp yelpings; which commence like the barking of a dog, and end in a sound resembling the cry of the peacock. Gestation continues for from sixty to sixty-five days. When the female is ready for parturition, she prepares a bed for her young with leaves and hay. She produces only once a year, and has from three to eight young at a time. The cubs are born like dogs, covered with hair, and having the

eyes shut, and continue growing for about eighteen months. If the dam perceive the place of their retreat to be discovered, she carries off her cubs, one by one, to a more secure habitation. At about three or four months old, the young foxes quit their burrow. They abandon their parents with all convenient speed, and at two years of age their growth is completed.

In the days of his inexperience, a favourite lure will ensnare him, but, when apprised of its nature, the same expedient becomes unavailing. He seems to smell the very iron of the trap, and carefully shuns it. If he perceives that the means of ambush are multiplying around him, he quits his place of residence, and retires into some more secure quarters. Man, with all his reasoning and machines, requires himself much experience not to be over-reached by the prudence and stratagems of this wily quadruped. If all the issues of the kennel are beset with snares, the occupant scents and recognises them, and, rather than fall into them, exposes himself to the most cruel and protracted privation of food. In confinement, this state of alarm is neither mechanical nor passive, for he leaves nothing untried to escape from danger; and, while a claw remains, he works at a new path, by which he often eludes the menaced ruin. In the fox, in short, as in the wolf, we may remark an aptitude to acquire habits, and to be regulated by his reflections on existing circumstances. He is comparatively ignorant and careless of his conduct when no war is waged against him; but, when the apprehension of pain or death, exhibited under various forms, has produced multiplied sensations, which become fixed in his memory, and give rise to comparisons, judgments, and inductions, he acquires skill, penetration, and cunning. If the imprudence and thoughtlessness of youth frequently make him deviate from the right path, the experience of age corrects his wanderings, and teaches him to discriminate true from false appearances. Foxes sleep much during the day, and lie, like the dog, in a round form. In very warm and clear weather, he may sometimes be seen basking in the sun, or amusing himself with his fine bushy tail. Magpies, crows, and other birds, which justly consider him as their common enemy, will often give notice of his presence by the most clamorous notes, and follow him a long way repeating their outcries.

The fox's skin is furnished with a soft and warm fur, which, in many parts of Europe, is used for muffs, boas, and lining of clothes. Vast numbers of foxes, on this account, are taken in the Valais, and the Alpine districts of Switzerland, inasmuch, that a Lausanne furrier is sometimes in possession of two or three thousand skins, all procured in the course of a single winter. Vast numbers of them are likewise imported from Newfoundland and Hudson's Bay. Notwithstanding the rankness of the fox's flesh, the natives of the latter country eat it; and even the inhabitants of some parts of the continent of Europe have recourse to it, during the vintage, when the animals are fattened with the grapes.

Fox-hunting, it is almost superfluous to mention, is a very favourite diversion with many of the nobility and gentry of this country, and that it is more zealously and successfully prosecuted in England than in any other country in the world. When the fox finds himself pursued, he generally makes towards his hole, and, penetrating to the bottom, lies till a terrier

is sent in to him. Should his den be under a rock or the roots of trees, the terrier is no match for him, and it would be no very easy matter for his enemies to dig him out. His stratagems and shiftings are as surprising as they are various when the retreat to his kennel is cut off, for he betakes himself to the woods and coppices of the country, and prefers the paths that are most embarrassed with thorns and briars. When before the hounds, he runs in a direct line, and, if hard pushed, resorts to the low wet grounds, as if conscious that, in such situations, the scent is with more difficulty traced. He becomes obstinately desperate when overtaken, and will turn on his adversary, and defend himself to the last gasp. The severest blows will not make him loose his hold; and he fights in silence until he is torn and mangled to death. Horses and dogs both, particularly the former, have very frequently fallen victims to the ardour of the chase, which sometimes has continued for eight or ten hours, almost at full speed, without the smallest interruption, and for a distance of forty or fifty miles.

The fox can be tamed, if taken when quite young, but seldom entirely loses his savage nature. Instances have, however, occurred of a domesticated fox showing nearly as much attachment to his master as a dog. The fox's olfactory nerves, as it is well known, are very acute. Like the dog and the wolf, he runs his game down by the scent. On the approach of a storm, or preparatory to a change of weather, he howls dismally. In the summer season the male, and more particularly the female, is very subject to cutaneous disorders; and it is asserted that, if a horse lie down on the spot previously occupied by a fox, he will likewise be infected.

Many anecdotes have been mentioned and recorded of the craft of the fox, and some of them place the sagacity of irrational animals in a very striking light, and perhaps none more so than those in which the crafty animal attempts

"To run away from death by dying,"

or rather, by counterfeiting death. One morning early, a man in the north was going to his work through furze bushes on a common, and came upon a fox stretched out at length under the side of one of the bushes. The fox was drawn out by the tail, swung right and left, and then laid on the ground, but not a symptom of motion or life did he show. The man, never doubting that reynard had gone the way of all foxes, and nothing loth to add a fox-skin cap to the list of his personal garniture, and the brush to the tale of peacocks' feathers, and other ornamental trophies, over the little looking-glass that stood inclined from the wall of his cottage, took the animal by the tail, and swung it over the one shoulder, at the same time placing his mattock on the other, to keep up the balance; and, having done so, onward he trudged to mend the high-road, for the accommodation of those who got foxes and their brushes in another way, which was his ordinary vocation. The two shoulderings were not exactly paired, and so the mattock began to assail the ribs of the fox in no very gracious manner. The animal had counterfeited death to admiration, and he did not mind being carried in the manner of a dead fox (it is remarkable that dead animals are usually carried with the head downward); but, dead as he seemed, he had no inclination to undergo that species of dissection which the point of the mattock was ever and anon giving his ribs. So

at last he gave that decisive snap, which we have described as the characteristic bite of foxes, on that portion of the labourer's rear which is supposed to be more sensitive to all manner of inflictions than any other region of the human body. The man felt that something was the matter, but knew not very well what; so, throwing fox and mattock from him, he turned round to face the foe, whoever he might be, and, in turning, he espied his dead fox at the distance of full fifty yards, making for the brake with all imaginable speed. The man was much annoyed at his adventure, and wished to conceal it; only, he told it to his fellow-labourer as a great secret, and thus, as is generally the case with secrets confided in this way, rendered it better worth telling than it otherwise would have been.

We shall mention one other anecdote, which came within the personal knowledge of the writer of this article, because it throws some light on the mode of action of the fox, as well as confirms the truth of his counterfeiting death in all cases where there is a likelihood that it may ensue. The parsonage of Kilmorac, in Inverness-shire, is situated in a highly romantic spot. It is near the brow of one of the precipices which form a gorge through which the river Beaulie has, in the lapse of ages, cut a deep channel through a great length of rock, thus emptying a lake which must at one time have occupied that singularly beautiful dell known by the name of the Dream of Kilmorac. The northern bank of this singular valley, or rather ravine, for it is something intermediate between the two, is richly wooded, and much of the sloping ground is a natural strawberry bed. It swarms with all those inhabitants, whether of the air or of the earth, which are found in warm and wooded spots of the Highlands. To render the collection complete, there are eagles in some of the towering rocks, near the lower part, and no want of goshawks anywhere; the hill beyond, too, is well stored with grouse, and as it is near the cultivated grounds, there are common hares as well as Alpine ones. Of course this is a very favourite retreat for foxes; and though the wild cats are said to keep them at bay, when they attempt to assail the preserve, they kennel in the margins, and infest the country around. The then clergyman of Kilmorac was a man of great taste, very fond of society, and very hospitable, and he accordingly endeavoured to provide for his numerous guests all the good things which his glebe land, on field or on hill, could afford.

A well-stocked poultry-yard is an essential requisite in such cases; but here foxes were so numerous, and their covers so near, that a poultry-yard was out of the question; and it was sometimes necessary to employ boys to "Hoo! hoo!" the fox even after the parson's pullets were turned out to range the fields. A poultry-house was thus requisite, and the Reverend Doctor prided himself not a little in having constructed one which was completely fox-proof; and for a good many years it had been impregnable to reynard, so that the Doctor's pullets and their eggs were known far and wide for their excellence, their abundance, and the frankness with which they were given to every one who courted the very pleasant society of their owner. A friend of ours had spent a night in this romantic and hospitable abode; and, while fresh salmon from the Beaulie, dressed in very delicious steaks, formed one article for the breakfast-table, new-laid eggs, from the strong-hold of the hens, were of course to form another. Christian, the purveyor in

these cases, took the key, and marched off, basket in hand, to bring the supply; but, when she opened the door, a scene of the most direful havoc presented itself. Every perch and nest-hole was bedabbled with blood, dead hens lay in dozens on the floor, and in the middle was a full-sized fox, stretched out at full length, and apparently a sharer in the common mortality. The maid never doubted the death of the fox, but attributed it to a different cause, namely, that he had so gorged himself on the poultry, as that he had burst. Here were three causes to rouse the mingled wrath and content of Christian. The fox had, by some means or other, shown that the place was not impregnable; there had been terrible havoc among the hens; and the fox had been gluttonous even to the death. She pronounced his funeral oration in certain most expressive Gaelic phrases, which we shall not quote, and will not translate; and then, without further ceremony, gave him a resting place, which she said was worse than a dog's burial. She took him up by the tail, and swung him with all her might into the receptacle in which were accumulated the requisites for garden compost. The fox fell softly, and rose again speedily, and, like Curll the bookseller in the Dunciad; he "scoured and stunk along," until he gained the cover of the woods, leaving Christian in utter consternation, and the minister minus both his pullets and the glory of his impregnable hen-house.

Common Fox.

The entrance to this place was by a stone some feet from the ground, with a little hole over it, and by this the fox must have gained admission, and so, gaining admission, he had killed every fowl that he could reach; and he must have killed them so silently and so suddenly, as that no noise or complaint on the part of any one had in the least alarmed the others. This is, we believe, the most striking peculiarity of the fox on his predatory excursions, and the above anecdote shows it in a very striking light, for there were perches so elevated that no fox could reach them; and as the pullets were in the habit of taking to them in other cases of alarm, of course they would have done so upon this invasion of the fox, if his deeds of slaughter had been attended with any noise. We have mentioned those anecdotes because they are characteristic, and we know them to be true.

The **BLUE FOX** or *ISATIS* (*V. lagopus*). This species occurs only in the arctic regions, a few degrees within and without the polar circle, particularly in Kamtschatka, and all the country bordering on the northern ocean. It is inferior in size to the preceding, and is sometimes to be met with entirely white,

though it is generally of a bluish grey colour. It is so very hardy as to prowls about for prey during the utmost rigour of the hyperborean winter. It subsists on young wild-geese, and all kinds of water fowl and their eggs, on hares, the smaller quadrupeds, &c., and frequently from necessity, on wild berries, shell-fish, or other substances rejected by the sea. They, in some regions, burrow in the earth, and form holes many feet in length, strewing the bottom with moss; but where the ground is seldom quite free from frost, as in Spitzbergen and Greenland, they live in the clefts of rocks, two or three inhabiting the same hole. They are in the habit of crossing from island to island, in quest of prey, being very excellent swimmers. They are caught in pitfalls, springes, or traps, baited with capelin or a bit of flesh, for the sake of their skins, which form a light and warm, but not a durable fur. The most interesting account, by far, which we know of the manners of this species, is that which Steller relates; but we shall only give a part of the passage to which we allude. "When we made a halt to rest by the way," says Steller, "they gathered around us, and played us a thousand tricks in our view; and when we sat still, they approached us so closely, that they gnawed our shoe-strings. If we lay down as if intending to sleep, they came and smelt at our noses, to ascertain whether we were dead or alive. On our first arrival, they bit off the noses, fingers, and toes of our dead, when we were preparing the grave; and thronged in such a manner about the infirm and sick, that it was with difficulty we could keep them off.

"Every morning we saw these audacious animals patrolling among the sea-lions and polar bears, lying on the strand, smelling at such as were asleep. If death happened to be the case, they proceeded to dissect him immediately, and soon afterwards all were at work in dragging the parts away. As the sea-lions, in their sleep, sometimes overlay their young, the foxes every morning examined the whole herd of them, one by one, as if conscious of this circumstance, and immediately dragged away the dead cubs from their dams.

"As they would not suffer us to be at rest by night or day, we became exasperated against them, young and old, and harassed them by every means we could devise. When we awoke in the morning, we always saw two or three that had been knocked on the head the preceding night; and I can safely affirm, that, during our stay on the island, I killed above two hundred of these animals with my own hands. On the third day after my arrival, I knocked down with a club, within the space of three hours, upwards of seventy of them, and made a covering to my tent of their skins. They were so unsuspicious, that with one hand one could hold to them a piece of flesh, and knock them down with a stick or axe in the other.

"From all the circumstances that occurred during our stay, it was evident that these animals could never before have been acquainted with mankind, and that the dread of man is not innate in brutes, but must be grounded on long experience.

"Like the common foxes, they were the most sleek and full of hair in the months of October and November; in January and February it was over thick; in April and May they began to shed their coat; in the two following months they had only wool on them, and appeared as if they went in waistcoats. In June they dropped their cubs, nine or ten at a brood, in holes or clefts of the rocks. They are so fond of their young, that to scare us away from them, they barked

and yelled like dogs, by which they betrayed their covert. But no sooner did they perceive that their retreat was discovered, than (unless they were prevented) they dragged the young away in their mouths, and endeavoured to conceal them in some more secret place. On one of us killing the young, the dam would follow us with dreadful howlings, by night and day, for a hundred versts or more, and would not even then cease till she had done her enemy some material injury, or was herself killed by him."

This species is very ragged and rough looking, during the process of changing its colour, and until near its conclusion. The change is no sooner completed, than the colour becomes uniform. It is of a pure white during winter. A dorsal line of a darker colour is observable in summer, with transverse stripes upon the shoulders, from which peculiarities it has been occasionally confounded with the cross fox. The paws are entirely covered with long hairs, and those on the other parts of the body are about two inches and a half in length.

Mr. Lloyd, in his "Field Sports of the North of Europe," describes the arctic fox as differing very materially from those of the common species. "He has," says Mr. Lloyd, "neither the cunning nor speed, and he is besides less cautious and timid." And according to the concurrent testimony of all travellers to the arctic regions, he is so little afraid of man that he may be readily knocked on the head with a bludgeon. "It has happened that this species has been killed in the most southern parts of Sweden; but it has been noticed that, instead of flying from his assailants, as is the case with the common fox, he has stood contemplating his approach until the fatal trigger has been drawn, and the loaded messenger has made him bite the ground."

This difference of character between the arctic and the common fox, points to a difference in prey and in manner of preying. In summer he appears to feed chiefly upon those birds which resort in such numbers to the bogs and borders of the northern marshes to breed; while in winter, when the birds are gone, and the waters frozen, he appears to resort farther upland, and subsist upon the small burrowing quadrupeds, of which there are vast numbers in that country, and many of which hybernate, and thus become an easy prey, just as the close-sitting birds do in summer when they are on their nests; the broad feet with which this species are furnished serve equally for traversing the bog in summer and the snow in winter; and the fur on the under part enables the animal to prowl with silent footfall, so as never to startle the game.

**BLACK AND SILVER FOX (*V. argentatus*).** The black and silver foxes are considered by the Indians to be the same kind, varying accidentally in the colour of the feet. The black are very rare, and fetch a very high price. Its skin is so rare, that Dr. Richardson says "a greater number than four or five are seldom taken in a season at any one part in the fur countries." The skins are sometimes entirely black, and are preferred when they have not any silver hairs in them; and when without any are considered the most valuable of furs, and are worth near 20% a skin.

This animal is often the size of the ordinary fox; in its entire organisation it closely resembles that well-known animal. The organs of sense, of dentition, and of generation, are the same, and its gait and movements exactly similar. It walks with its head and tail depressed. Its glances are pregnant

with distrust and penetration, and, in a word, it would be completely our European fox, if it were fawn-coloured instead of black and silver. The hair of the body and of the tail is long and tufted. Silken hairs widely dispersed, extremely fine, and of a grey, approaching to black, form the immediate covering of the skin, and the peculiar colour of the animal is owing to silken hairs which are generally of a brilliant black, though occasionally terminated by a white point, and

Black and Silver Fox.

sometimes, but rarely, altogether white. The extremity of the tail is almost entirely white, the fore part of the head and the sides are whitish, and some white hairs are detached, as it were, from all the other parts of the fur, and have no other effect than to set off to better advantage the lustrous brilliancy of the black, of which it is generally composed. The eyes are yellowish. These animals play like dogs, and like them, express their displeasure by growling. When the animal's hunger is satisfied, it conceals the rest of its food, lies down, and goes to sleep. It has a very disagreeable odour, but differs a little from that of the common fox. The exhaustion which it suffers from heat, sufficiently indicates the countries of which it is a native. Nearly all authors who have travelled in the northern parts of the old world, speak of black foxes, which has given rise to an opinion, in which there appears probability, that the species which we have been describing is to be found in both continents. Some doubt, however, must be preserved respecting their identity, until such time as it shall be confirmed by new observations, and a more exact comparison of characters.

Arctic Fox.

The foxes of the arctic countries, especially of Siberia and America, where they are most abundant, present nearly the same kind of difficulties to the systematic naturalist as the intermediately sized cats do in the tropical forests. They are all formed nearly alike, and do not differ much in size and strength; and thus the only palpable distinction is that of colour,

which of itself leads to nothing, as no means have yet been discovered by which the colours of animals can in any satisfactory way be connected with their habits.

**THREE-COLOURED FOX** (*V. cinereo-argenteus*). This is a native of the middle and southern regions of America. The name it may be observed might, in point of fact, be applied to the other species, as the white, the fawn colour, and the black are combined in the fur of almost all foxes. But improper as it may be, it must be retained, as it has been so long received, and as we are ignorant of the name which this animal bears in the middle and southern regions of North America. It is strange what very little care is taken by travellers to ascertain the proper names of the animals of those countries which they traverse, actually when the means of such information are entirely within their reach. The influence which such information must exercise on the progress of natural history, would give a double value to their researches. The history of any species can evidently be the result only of a very long series of observations, which it is utterly impossible for any single individual to make. To the first observations of this description the second should be naturally attached, for the purpose of giving them their just portion of utility, the third to the second, and so on, until all the necessary information is acquired. We are liable without some such plan to endless repetitions, which can produce nothing but regret for the labour which has been expended on them. The knowledge of the native name, in fact, is essentially necessary to enable us to know of what animal any traveller speaks, and of which, in all probability, he cites but a few characteristics, very insufficient for the purposes of a clear distinction. The ancients on this point seem to have been much more careful than the moderns. Such reflections as these are sure to suggest themselves to the mind, when we come to consider the foxes of North America. There are few animals of which travellers have spoken more, but there are few whose history has been treated of with less detail, and with less attention to any thing like method.

From the range of latitude over which foxes having the colours upon which this name is founded extend, we may naturally suppose that there are many varieties of colour among them. The most common markings are described thus: Upper parts of the body greyish black; head greyish yellow; ears and sides of the neck bright red; throat and cheeks white; skin black; abdomen yellow; tail yellow brindled with black and wholly black at the tip. This species or variety has been described as a South American animal by D'Azzara; and as a North American one by various authors. Its colours are those of several of the other coloured varieties blended; and therefore it may be a mongrel of many breeds, which word, as in the case of dogs, is in our opinion far more applicable to the differently coloured foxes, than the word "species," or even the word "variety." The distinctions between them are all too small for being useful in natural history.

**THE RED FOX** (*V. fulvus*). This species is not absolutely red, but of a bright reddish brown or orange. It is a native of North America, and belongs to the class of foxes which, in locality, may be considered as intermediate between the arctic ones and those of the warmer latitudes. It was long supposed that this was merely a coloured variety of the common fox; but a fine specimen presented to the Zoological

Society of London by Lord Clinton, afforded an opportunity of contrasting the two, and the following are Dr. Richardson's remarks:—

"On comparing a fine specimen of the English fox with an American fox, each was observed to have dark markings on the sides of the muzzle, posterior parts of the ears, and fore parts of the legs; the tails of both have an intermixture of black hairs, and are tipped with white. The red fox, however, differs in its long and very fine fur, and in the brilliancy of its colours. Its cheeks are rounder, its nose thicker, shorter and more truncated. Its eyes are nearer to each other; its ears are shorter; the hair on its legs is a great deal longer; and its feet are much more woolly beneath, the hair extending beyond the claws, which are shorter than those of the European fox. In short, the red fox differs from the European one in nearly the same characters that distinguish the grey American wolf from the Pyrenean one, in the breadth and capacity of its feet for running on the snow, the quantity of long hair clothing the back part of the cheeks, which in conjunction with the shorter ears and nose, give the head a more compact appearance. The red fox has a much finer brush than the European one, and is altogether a larger animal."

There are, however, so many foxes in the wilds of America, especially in the northern part of that continent, and they differ so much in colour in some of the specimens, approach so nearly in others, and are so exactly the same in structure, and so nearly the same in manners, that it would be no easy or perhaps even possible matter to form a systematic arrangement of them; and after such an arrangement had been formed with the greatest care and discrimination it would be of very little value; because it belongs to that class of minute distinctions which lead to no conclusion, and which are serviceable only in so far as they enable the showman to give a different name to every animal in his living collection, or to every skin in his museum, which may happen to have different colours and markings from others. The following observations by the eminent naturalist from whom we have just quoted, are very much to the purpose. "Foxes," says Dr. Richardson, "are distinguished by the traders under the names of black, silver, cross, red, and blue foxes. The two former are considered by the Indians to be the same kind, varying accidentally in the colour of the pelt. The black foxes are very rare and fetch a high price. The cross and red foxes differ from each other only in colour, being of the same shape and size. Their shades of colour are not disposed in any determinate manner, some individuals approaching in that respect very nearly to the silver fox, others exhibiting every link of the chain down to nearly a uniform deep or orange-yellow, the distinguishing colour of the pure red fox. It is reported both by the Indians and traders, that all the varieties have been found in the same litter. The blue fox is seldom seen here, and is supposed to come from the southward." The case of the fox is by no means a solitary instance of confusion introduced into the nomenclature of animals, by those who hunt wild ones without any reference to science.

**THE LITTLE YELLOW FOX** (*V. corsac*) is smaller than the common fox, and the localities which it inhabits are of a different character. It is not found in woods or thickets, but in the open wastes. With some differences of appearance, it seems to extend from the steppes of Siberia to central Africa; and may be the

"little fox" alluded to in the bible, though the accusation against the little foxes there is that they "spoil the vines," and there are no vines, at least in the native localities of this one. The general colour is greyish yellow, with some waving streaks of black at the root of the tail, and the tip of the tail is also black. The place where this fox has been seen in the greatest abundance, is on the steppes between the mountains of Ural and the west end of the Altaian chain. They are so numerous on the wide plains there, that according to Pallas, not fewer than fifty thousand skins have been procured in a single season in the province of Orenburg alone. They are also found very abundantly on all the dry and extensive plains of central Asia, and appear to follow the line of the arid wastes on the margin of the deserts as far as the sources of the White Nile. It is probable that they are found also on the dry plains of the north of India; but the fox of the south of that country, or of the Deccan, is described as being somewhat different. The following is the account of it, as given by Colonel Sykes, to whom we are so much indebted for a knowledge of the animals of the Deccan.

The KOKREE (*V. kokree*; *Canis kokree*, Sykes.) "Upper part reddish grey, under dull white, tail brushy, with the tip black, feet reddish, and pupil of the eye elongated.

"The fox of Dukhun appears to be new to science, although it much resembles the descriptions of the corsac. It is a very pretty animal, but much smaller than the European fox. Head short; muzzle very sharp. Eyes oblique; irides nut brown. Legs very slender; tail trailing on the ground, very bushy. Along the back, and on the forehead, fawn colour; with hair having a white ring near to its tip. Back, neck, between the eyes, along the sides, and half way down the tail, reddish grey, each hair being banded black, and reddish white. All the legs reddish outside, reddish white inside. Chin and throat dirty white. Along the belly reddish white. Ears externally dark brown, and with their fur so short as to be scarcely discoverable; edges of eyelids black; muzzle red brown." The length from the muzzle to the tail is from twenty-two inches to twenty-two inches and a half; and that of the tail itself from eleven inches and a half to a foot. The foxes of the corresponding latitudes of Arabia and Africa have not been examined with much care; but from the account given by Rüppell, it should seem that the Nubian fox very closely resembles this one, and that they differ from the small fox of the dry plains of the northern and central plains of America, chiefly in being smaller in size and having the fur on the body less produced; but, even in the warmest latitudes, they retain their brush in its full perfection, which shows that this peculiar production of the tail and its covering answers some very important purpose in the economy of foxes, though what this purpose is has not hitherto been ascertained,—indeed, we want a good philosophical account of the tails of animals.

The CAPE FOX (*V. mesomelas*). This species from its name is, of course, South African; and it appears to resemble the last-mentioned in some particulars; though there are some doubts about it. It has a long bushy tail, and elliptical pupils according to some; while, according to others, the pupils are round. If the first are correct, it is a fox; if the second, it is a jackal.

The CROSS FOX (*V. decussatus*), is considered by Cuvier as only a coloured variety of the common fox,

which it resembles in size and in manners; but, in our uncertainty as to the species of foxes, it is worthy of a separate notice. The prevailing colour on the upper part is blackish grey, produced by hairs with alternate rings of white and black. This colour also extends to the outer parts of the legs, but these have less white. There is a black cross on the shoulders, from which the trivial name is obtained. It has been principally found in North America, where it inhabits far to the northward, and is found on the shores of the Arctic Sea, not only on the American side of the Straits, but also on the Siberian. Indeed, from the proximity of the two continents at this place, from the ice in the strait forming a regular bridge every winter, and there being a permanent one from thence to the north, it is natural to suppose that foxes which, though not migratory, are ranging animals, and which, as they do not migrate, may naturally be supposed to disperse in the winter, when food for them is not abundant in any one locality, will pass readily from the one continent to the other, so as to be very little different in both. They also, in all the species probably, are subject to seasonal varieties, both in the length and closeness, and in the colour of the fur. Thus at certain seasons, or at all events, in certain individuals, the fox, which is usually called white and silver, from the grey on the points of the hairs, is found entirely black. In this state it is rare, and this also seems to be the prime condition of the fur in point of beauty; the old coat entirely gone, and the new one fully grown, but not begun in the least to fade or become dry, so that it has more gloss than at any other period. It seems also, that, whatever may be their variety as to colour, foxes acquire a much thicker winter covering, in proportion as they inhabit places which are colder, and this not only over the body, but on the soles of the feet. Not on the pads, because these are not fitted for producing hairs, as they are without the papillæ from which those appendages grow. But the inner and under sides of the toes, and the spaces between the pads, produce fur of so lengthened a character, that it seems to cover the entire sole of the foot, at least that part of it which comes in contact with the snow. The numbers of those animals in the northern regions are immense; their skins are of great value; and we believe that their flesh is very wholesome, and might be cleared of the foxy odour by being buried a short time in the ground. The northern people are not, however, very delicate in their tastes.

FOX-BANE. Is the *Acquittum vulparia* of Reichenbach, a common plant found wild on the European alps, and belongs to the natural order *Ranunculaceæ*.

FOX-GLOVE. Is the *Digitalis purpurea* of Linnæus, a handsome and very common British plant, abundant on hedge-banks everywhere. It belongs to *Scrophularinæ*.

FOX-TAIL GRASS. Is the *Alopecurus pratensis* of Linnæus, one of our most useful meadow-grasses, and one of the principal species employed in laying down permanent pastures.

FRAGARIA—Strawberry. A genus of European herbs, yielding delicious fruit. The flowers are icosandrious, and belong to the natural order *Rosaceæ*. The strawberry has been long in cultivation, and many excellent varieties have originated under the practical skill and care bestowed on their culture. The best and most convenient season for forming a new plantation of strawberries is the month of Au-

gust, because then the young plants produced on what are called runners from the old stocks are fit to be separated from the parent, each having roots of its own. The best soil for the generality of the varieties is a mellow loam, but almost any kind of garden soil in good heart is suitable. The ground intended to receive them should be trenched or double-dugged, and the surface enriched with some good rotten dung. The usual order of planting is on beds of four and a half feet wide, on which four rows of plants at twelve inch distances between are dibbed at like distances between plant and plant; this allows margins of three inches on each side. The beds are separated by two feet wide alleys, to allow of weeding, watering the plants, and of gathering the fruit.

The strongest runners are always chosen for transplanting, and in order to obtain them as strong as possible a shallow trench is made between the rows of old plants, and filled with a rich compost. On this the first runners are laid and fastened down by little hooks. The runners quickly strike roots into this compost, and grow strongly. To encourage them still more they should be watered along with the mother plants in dry weather. When the season arrives for transplanting, the young plants rise with fine roots, and strong enough to promise a good crop in the following year.

The beds are never dug between the plants, but only kept clear of runners and of weeds by the hoe. The alleys are dug every winter, and a little of the fresh soil from them thrown over the beds as a top-dressing. It is usual to lay straw, or some kind of clean loose litter, round the plants before the fruit begins to ripen, to save them from being dashed with earth by rain or when watered. When young plants are not wanted, the bearing plants should be kept free from runners lest they rob the swelling fruit.

This plan of keeping every mother plant distinct and separate, is most suitable for the larger sorts; the alpine, and sometimes the *hautbois* are planted individually at first, but afterwards allowed to run all over and occupy the whole surface, in which state these kinds will, in somewhat shady situations, do very well, and continue productive for several years.

Some cultivators, instead of beds, plant the large sorts in open order, say two feet apart every way on well prepared ground, knowing that the more space each plant is allowed the stronger it will grow and flower, and bear fruit in greater numbers, and of greater size. Besides, the side branches of the mother-plant (not the runners) have room to extend and yield fruit in as great quantity as the principal crown. To understand this result rightly, it is necessary to advert to the constitutional character of the strawberry plant. The plant is compound; that is, it is composed of a principal and central division, which yields flowers and fruit in the next year after it is formed. This principal is surrounded by a secondary set of branches, which also in time yield flowers and fruit superseding the first, which decays and disappears after it has ripened its fruit. The secondary set of branches, or divisions, of the system put forth, in their turn, a tertiary birth of branchlets, which also in time are fruitful: and these again a fourth set of offsets, which process is continued for ever, if the plants are not destroyed by accident or by each other. During this process, the system from this annual subdivision becomes weaker and weaker, so that at last the flowers are so few and

diminutive, that the crops are unprofitable, and not worth their place in the garden.

This is so well known to cultivators, that they do not consider a strawberry plantation worth its place after the third year, and many take only two crops from the plants, trenching them down as soon as the crop of the second year is gathered. Here it may be asked, how is it that plants allowed to occupy the whole surface of the ground are suffered to be usurpers? The answer is,—to save trouble, and as some of the runners are always yielding fruit for the first time, these being passable as to size and flavour, guarantee the preservation of the whole.

Strawberries are often planted in single rows by way of edgings to borders. In this way they have the advantage of full air and light, which is so far suitable, as well for increasing the size, as for the convenient gathering of the fruit. People of fortune, who wish to have the fruit in the highest perfection, are at the expense of paving the whole surface of the beds, leaving holes for the reception of the plants. Others erect beds of brick-work formed like a ridge, the sides graduated like steps, on which the plants are placed in apertures left to admit the roots into the compost on which the bricks are laid. These beds have a contrivance for the purpose of irrigation, which is of great service during the flowering season. There is a trough formed of the brick-work along the ridge, which being intentionally leaky allows the water to percolate down the sides without wetting the flowers or fruit. The reflected light of the sun from the bricks serves also to ripen and improve the flavour of the fruit.

Potted strawberry plants may be forced either on hot-beds, pits built for the purpose, or in almost any description of forcing-house, provided air, light, and water enough can be given. On hanging shelves in a peach-house or vinery they do well, so as they are kept as near the glass as possible, and be not placed in pans, stagnant water being hurtful to the roots.

Strawberry plants which have been forced are often consigned to the rubbish heap, but by bestowing a little care on them they may be made doubly serviceable. It should be considered that the primary bud of the crown has only yielded fruit, and the secondaries being at the same time advanced, they therefore only require to be turned out of the pots into good soil, in a north or east aspect, where they will make new roots, and give a small crop of fruit in the autumn. This crop, indeed, is neither so large nor so finely flavoured as the summer fruit, but they give variety to the dessert, and are always useful to the confectioner.

An autumn crop of strawberries may be obtained by a very simple expedient; viz. by divesting the plants of all their first flowers, which will cause those of the side branches to be soon afterwards developed, and which will give their fruit in the autumn. This will, however, be at the expense of the next year's crop.

The most esteemed sorts of strawberries are the following, viz. :—

The *Alpine* red and white are both of weakly growth, and yield fruit from well-established plants from the end of June till November. A light chalky soil suits them best; and as they succeed the earlier sorts, they are usually planted on north borders, in order to prolong their fruiting season.

The *Virginian*, or scarlet pine, is universally cultivated: it affects a strong and rather rich loam; is

an early sort, and forces well. It requires an open airy situation.

The *Roseberry* is a variety of the preceding: very fruitful, and grows to a large size. This also requires rich loam and an open situation.

The *Chili* bears a large and well-flavoured fruit, but without much colour. It grows strong, and requires ample space and good ground.

The *Keen's seedling* bears a large showy fruit, and is much esteemed in the market as well as at table.

The *Pine* is a new variety, and much cultivated in the neighbourhood of London. It requires to be planted singly in very open order. A loamy soil and open exposure is most suitable to both this and the *Imperial*, a kindred variety also much esteemed.

The *Hautbois* is an old sort, valued for its high and peculiar musky flavour, and when well grown is certainly one of the best. There is a peculiarity in the flowers of this sort unlike its congeners; some of the plants being destitute of female organs—of course barren. These barren plants, however, are not without their use, for it is found, if duly interspersed with the others which are defective in their stamens, good and plentiful crops will be obtained. In making a new plantation of the hautbois, both the male and female plants should be carefully mixed in the rows to insure success. Air and light are particularly necessary to this sort; and if the flowers and trusses of fruit be tied up to little stakes, so that they may be above the leaves, matures them perfectly.

There are several other new varieties of strawberries lately brought into cultivation; such as Knyvett's *New Pine*, *Grove End Scarlet*, *Downtons*, &c., all requiring similar management.

Soon as strawberries begin to be scented, they are eagerly preyed on by snails and slugs, to the depredations of which their position near the ground and dense covert of foliage subject the fruit. To prevent these animals harbouring about the plants, the beds or rows should be two or three times, during the months of March and April, well watered with lime water. This will, probably, either kill or banish them before the fruiting season.

**FRANKENIA** (Linnæus). A genus of creeping perennials found in different parts of the world, two of them being British. One is called sea heath, and belongs to the sixth class of Linnæus, and the natural order to which they give a title is described beneath.

**FRANKENIACEÆ.** A natural order, containing only a few genera and species, chiefly hardy herbs,

of the valves. They are plants of no beauty, and have no known medicinal qualities.

**FRATERCULA**—Puffin. A genus of web-footed birds, belonging to Cuvier's division of *Brachypteres*, or short-winged birds; and generally, though improperly, included in the genus *Alca*, the penguin; but the characters are sufficiently different for warranting the separation of this species from the others.

The following are the generic characters: bill shorter than the head, deeper than long, and much compressed; both mandibles arched, transversely channelled, and notched towards the tip, the upper sharp-ridged and elevated above the level of the skull; the nostrils lateral, marginal, linear, naked, almost wholly concealed by a large naked membrane; legs short, placed far behind, furnished only with three toes, all directed forwards and webbed, claws much hooked; wings short.

In their general habit they bear some resemblance both to the guillemots and the penguins; but they are less addicted to flying than the former, and, generally speaking, better winged than the latter, with the exception perhaps of the common auk or razor-bill. They, however, skim along the surface of the sea with considerable swiftness; but they are bad walkers, and not found inland, though of course they, like other birds of the same class, resort to the shores in the breeding time.

They are all inhabitants of the colder seas of the northern hemisphere; there being at least three species, one more common on the north of the Atlantic, another on the north of the Pacific, and a third on the shore intermediate between the two oceans, at least in the American part.

**COMMON PUFFIN** (*F. arctica*). This species is well known upon many parts of the British coasts; and its singular appearance and loud screaming cry have got it an endless number of local names, to which, in the case of this bird, it is necessary to pay some attention, although it is so constant to its type that when it is fairly seen there is no chance of mistaking it. The following are the characters: the bill compressed, two-edged, upper mandible with three grooves, the under with two, orbits and temples white, upper eyelids daggered or furnished with a pointed callus. The mature male and female, both in their winter and summer dress, have the crown of the head, all the upper parts, and a broad collar, deep and glossy black; the quill-feathers dusky brown; the breast, belly, and lower parts, pure white. Length about twelve inches and a half, extent of wing twenty-one inches, weight about twelve ounces. The bill, which imparts such an appearance of novelty to this bird, varies considerably according to its age; for in the first year it is small, weak, destitute of any furrow, and dusky; in the second year it is larger, stronger, of a paler colour, and discovers a faint vestige of a furrow near the base; but in the third and more advanced years it exhibits great strength and vivid colours. The whole plumage is remarkable for its closeness; and the bird is very compact in its form; and when it sits on the point of a rock, just above the surface of the water, with its head in the position which heralds call "regardant," it makes rather a handsome appearance, as may be seen in the representation beneath. It does not appear that these birds, notwithstanding the great power of their bills, prey upon large fishes, though in all probability they consume vast numbers of the

*F. pulverulenta*.

nearly allied to *Caryophylleæ*, from which it is distinguished by the fruit not having a central separate placenta, but bearing the seeds on the inner margin

small fry, because they are observed to be very active in those turbulent states of the water near the shore, in which the fry lose command of themselves, and are easily captured. Their principal food, however, seems to be the smaller crustacea and shelled mollusca, and the great strength of their bill enables them readily to bruise the former, and break the shells of the latter. In respect of their feeding, they probably form one extreme of the diving birds, being less officious than any of the others, but having the bill better adapted to act as a bruising instrument than any other sea birds whatever. They use the bill, and that very powerfully, in their own defence; but except in the breaking up of that small food on which they subsist, it does not appear that they use it for any purpose of attack.

Common Puffin.

Puffins are abundantly found in all the northern seas of Europe, Asia, and America, and there are many of them, during the summer at least, on the shores of Spitzbergen; but of course they retire from those northern haunts during the winter; and indeed at this season they quit the neighbourhood of their nesting places, and become discursive over the sea, as is the case with all those aquatic birds which resort in great numbers to particular spots of the coast during the breeding season. In their southern progress they have been found about Belleisle, in the Gulf of Gascony. As they take flight with great difficulty, they are sometimes run down by boats, or driven ashore, when suddenly caught in a gust of wind; but they can fly very well when they get on the wing. They appear in many parts of our rocky coasts about the middle of April, and commence breeding towards the middle of May. On the Dover cliffs, and other such places, they deposit their single white egg in the holes and crevices; but in other situations they burrow like rabbits if the soil is light, or more frequently take possession of a rabbit's hole, and lay their egg some feet under ground. On St. Margaret's island, off St. David's, the fishermen put their hands into the holes, and the puffins seize them so obstinately, that they allow themselves to be drawn out. The Orcadians drag them out with a stick, to the end of which is attached an iron hook. The flesh of the old bird is both rank and fishy, but the young ones, which are seized before they are quite fledged, when pickled and preserved with spices, are much relished by some, and are allowed to be eaten in Roman Catholic countries during Lent. In some places they are taken with ferrets. The males, as well as females, perform the office of sitting, relieving each other when they go to feed. The young are hatched in the beginning

of July, and the re-migration of the species takes place about the middle of August, when none remain behind, except the unfledged young of the latter hatches. In one part of Akaroë, a small island off Iceland, puffins breed in vast numbers, forming holes in the mould three or four feet beneath the surface.

In the Faroe islands puffins are also very numerous; and the young, and indeed the old birds, are eagerly sought after as articles of food; in the capture of these birds, and the other nestlers in the rocks, the Faroese undergo the greatest hardships, and expose themselves to the most imminent dangers. The following account of their labours in this way, chiefly drawn up by Sir George Mackenzie, who visited these islands in 1812, cannot fail to be read with interest. "The fowlers," says Sir George, "are provided with long poles, to the ends of which are fastened small rope nets. With this instrument they generally display great dexterity in casting it over the birds, which invariably make towards the water when disturbed. It is this anxiety of the birds to seek the element in which their security is to be found, which gives certainty to the exertions of the fowler. The birds push their heads through the meshes of the net, which, being dexterously inverted, keeps them suspended by the neck. When a fowling expedition is undertaken, two men fasten themselves to a rope, so that there may be eight or ten fathoms of it between them. One assists the other to ascend the rope by means of a pole, at the end of which is a hook, which is fastened to the band of the climber's breeches, or to a rope tied round his waist, and thus he is pushed up; but the most common method is for the climber to seat himself on a board fastened to the end of the pole. They often ascend frightful cliffs without any assistance. When the first has got to a place where he has some footing, he helps the other up by means of the rope to which they are both fastened. When they have gained the elevation where the birds are pretty numerous, they assist each other from cliff to cliff. It sometimes happens that one of them falls and pulls the other after him, when both are precipitated into the sea, or dashed to pieces on the projecting rocks. When the rocks are so high and smooth as to render it impossible for the fowlers to ascend, they are let down by means of a strong rope from above. To prevent the rope from being cut, a piece of wood is placed at the verge of the precipice. By means of a small line the fowler makes signals to those above, and they let him down or pull him up accordingly. When he reaches a shelf of the rock where the birds have their nests, he unties himself, and proceeds to take them. Sometimes he places himself on a projecting rock, and, using his net with great adroitness, he catches the birds as they fly past him, and this they call veining. This mode of catching birds is even practised while the fowlers are suspended. When a projection of the rock is between the fowler and the place where the birds are, he swings himself from the rock so far that he turns round the projection. In this, great address and courage are requisite, as well as in swinging under a projection into a cavern. When he cannot with the help of his pole swing far enough, he lets down a line to people stationed in a boat below, who swing him by means of it as far as is necessary to enable him to gain a safe place to stand upon. Besides being exposed to the risk of the rope breaking, the fowler is frequently in danger of being crushed by

pieces of the rock falling down upon him." The eggs of the common puffin are also held in considerable repute as articles of food; but as there is only one in the nest hole, as that hole is deep, and as after the egg is dropt one of the birds is usually there, prepared to seize whatever is intruded, the plunderer of a puffin's nest requires either hard fingers or a thick glove. With either of these, however, the bird may be easily drawn out.

THE CRESTED PUFFIN (*F. cirrata*) has the upper part of a bluish black, and the under dull brown; the front, the sides of the head, the chin, and part of the coverts, pure white. There are tufts of long thread-like feathers which rise over the eyes, and dividing into two parts, bend over the sides of the neck. These feathers are white at their bases, but yellowish at their points. There are three furrows in the bill; and a cartilaginous cere at the base of the bill, forming a sort of rosette at each angle of the gape; the tarsi and toes are bright orange-yellow, the webs of the feet red, and the claws black. These are the characters of the male bird; and the length of that species is about nineteen inches. The female is rather less, has a smaller crest, and has only two furrows in the bill, but in other respects the sexes are pretty similar.

This species is chiefly found in the sea of Kamtschatka, both on the American and the Siberian side, and also on the shores of the Aleutian islands; but it is probable that, like their congeners of the Atlantic, they migrate southward during the winter. Their bills are even more powerful than those of the others, but their food is nearly the same, being chiefly crustaceous animals and shelled mollusca. They are exclusively-day feeders, and though, like the former, they are sometimes found sitting on rocks watching for their prey, they seldom come to land, except during the night. They lodge in holes of the rocks, or in burrows which they themselves excavate in the dry banks, which are generally between three and four feet deep, and no wider at the entrance than will just admit one of the birds, but farther in it is wider. One egg only is produced at a brood, which is rather larger than that of a common duck. This species and the former are not found in the same seas; and though their manners are very similar, they appear to be properly entitled to rank as distinct species.

NORTHERN PUFFIN (*F. glacialis*). This species inhabits more northerly than any of the others, and has not been observed except in the Polar Sea, or even there, but on the north coast of America. Among the dreary islands in that region it is, however, one of the most northerly birds. The upper part of it is black, with a collar nearly as large as that of the common puffin; the cheeks and sides of the head are greyish white; the quills brown; the under part white; the upper mandible of the bill very much elevated, and with three furrows; the inferior mandibles strongly arched; the feet orange-yellow; webs red; and the claws black. The length is nearly the same as that of the common species, being about a foot or thirteen inches. The probability is that its manners differ but little from the one with which we are familiar on the shores of this country; but there is not much known respecting it.

FRAXINELLA. Is the *Dictamnus fraxinella* of Persoon, an ornamental herbaceous perennial, a native of Germany, a border plant in flower gardens, and is easily propagated by seeds.

FRAXINUS (Linnæus). A genus of hardy deciduous trees, natives of Europe and North America. They are polygamous, and belong to the natural order *Oleaceæ*. Generic character: calyx four-parted or none; corolla of four petals four-parted or none; stamens short, anthers oval, two-celled, bursting outwardly; stigma nearly sitting, bifid; fruit two-celled, compressed, winged at top. For an account of the mode of cultivation, see *ASH*.

FRINGE TREE is the *Chionanthus Virginica* of Linnæus. A deciduous flowering shrub or tree, a native of North America. The flowers are elegant, and the plant has always a place in ornamental plantations.

FRINGILLIDÆ—the Finch family. A very numerous and interesting group of small birds, in some or other of its many species, inhabiting all parts of the globe, and constituting the tribe or sub-order *Conirostres* of Cuvier. They are all seed-eating birds, some, however, being much more exclusively so than others, whose grand office in the economy of nature is to assist, and that in no small degree, in keeping down the excess of certain forms of vegetation, subsisting on the germs of life, so copiously and abundantly distributed by various plants, chiefly of the composite and cruciform races, the extreme and exuberant fertility of which would otherwise enable them to usurp dominion over every other, and so monopolise the soil as to render it unfit for cultivation. The adaptation, however, as in all other similar cases, is of course mutual, and the apparent superfluity of seeds which are annually produced thus enables thousands and millions of beings to enjoy existence—to enliven and diversify the face of nature with moving life, and to cheer the still monotony of vegetable beauty by their lively and inspiring songs of joy and happiness. They, in their turn, furnish food to other races; and there are several of the smaller birds of prey which draw their chief subsistence from the various tribes, which, together, constitute the comprehensive and very natural *family* of which we have now to enter upon a description.

The general character, or that which is the most typical of the group, is to have a sharply-pointed, conical, and, in most cases, a strongly-formed bill, the upper mandible of which advances a little upon the line of the forehead; the *tomia*, or cutting edges of the mandibles, are always more or less bent inward, those of the under one more particularly; and the bill is endowed with great power of compression, the mandibles having a separate motion, and the under one having besides, a considerable lateral movement, by means of all which, and with the assistance of the tongue, the birds are enabled to crack with facility the husks of very hard seeds, and to shell them, rejecting the envelope while the kernel remains in the mouth; the feet have three toes before, and one behind, all of which are entire, and separate to their full extent, and they are adapted either for perching, or for progressive movement; upon the ground, this movement is, in most of the species, performed by hopping, though some of them can move forward only by alternate steps, while a few advance alike by either method; these latter, however, have neither movement in such perfection as those which are confined to one only.

As a group, the plumage may be described as being generally of a firmer texture than in the insectivorous races, their colours and markings being more decided, and the male is in almost every

instance clad in a much brighter livery than the hen bird, the difference being most conspicuous in summer, as at the autumnal renovation of plumage the new feathers are each fringed with a dusky edging, which gradually wears away from the bird in the ensuing season.

The species are, however, so very numerous, that it is difficult to mention any general character which will apply alike to the whole group, which therefore can be satisfactorily described only in its subordinate divisions separately. There are five or six leading modifications in the form of the bill, some of which are accompanied with very slight differences in the other general characters. The family may be said to commence with the *Tanagrina*, or *Tanagers*, a division pertaining exclusively to the American continent, and comprising several genera and a considerable number of species, most of which are adorned with splendid, some with most gaudy, colours, and which are by far the most insectivorous of the finch family, subsisting chiefly upon beetles, grasshoppers, and the other larger insect tribes; but they shell grain with the same facility as the other *Fringilidæ*. In this division, as might be expected, we find many traces of the *Dentirostral* character (see article BIRD); and indeed there is a regular and unbroken series of forms connecting these birds with certain of the cotinga family (*Ampelidæ*), a group belonging to the *Dentirostres*, and the great majority of members of which inhabit the same countries, and display equally rich and showy plumage with the *Tanagrina*. In one genus of the latter, *Pyreya* of authors, the *Dentirostral* character is indeed pretty well made out; but this division will be more conveniently described in detail in a separate article. **TANAGER.**

Painted Nonpareil.

Immediately following these, and connecting them with the more typical finches, we have the genus *Spiza*, of C. L. Bonaparte, also inhabiting the new world, and containing birds of very bright and showy plumage. Its characters are intermediate between those of the *Tanagers* and more typical finches; and, like the former, they would appear, from Wilson's description of his "painted beauties" (or, to give it a more definite name, painted nonpareil, *Spiza cisia*),

to be very insectivorous. This gaudy little bird is often imported into this country, and live specimens of it may be procured at several of the London shops in which foreign birds are kept for sale. It is about the size of a goldfinch; the head, and upper part and sides of the neck, are bright purplish blue; eyelid, chin, and all the under parts, vermillion; back and scapulars glossy yellow, stained with rich green, in the older individuals with red; lesser wing-coverts purple; larger green; wings dusky red, sometimes edged with green; rump and tail-coverts bright red; tail, which is slightly forked, sometimes of a purplish brown, sometimes green; legs and feet leaden grey; bill black above and bluish below; irides brown. Such are the brilliant tints of one of the commonest birds of the more southern of the United States of America.

These birds are caught in great numbers by the American bird-catchers, and kept in confinement on account of their beauty. The mode of catching them is somewhat curious, as described by Audubon:—"A male bird, in full plumage, is shot, and stuffed in a defensive attitude, and perched among some grass-seed, rice, or other food, on the same platform as the trap-cage. This is taken to the fields, or near the orangeries, and placed in so open a situation that it would be difficult for a living bird of any species to fly over it without observing it. The trap is set. A male painted finch passes, perceives it, and dives towards the stuffed bird, brings down the trap, and is made prisoner. In this manner thousands of these birds are caught every spring; and so pertinacious are they in their attacks, that, even when the trap has closed upon them, they continue pecking at the feathers of the supposed rival."

This species is described by Wilson to be one of the most numerous of the little summer birds of Lower Louisiana, where it is universally known among the French inhabitants, and called by them *le Pape*, and by the Americans *the Nonpareil*. "Its gay dress and docility of manners," he says, "have procured it many admirers, for these qualities are strongly attractive, and carry their own recommendation along with them. The low countries of the southern states, in the vicinity of the sea, and along the borders of our large rivers, particularly among the rice plantations, are the favourite haunts of this elegant little bird."

The same naturalist has furnished us with a detailed account of another species, the *Indigo Nonpareil* (*Spiza cyanea*), another beautiful summer visitant of the United States. "This is another," he observes, "of those rich-plumaged tribes that visit us in spring from the regions of the south. It arrives in Pennsylvania in the second week in May, and disappears about the middle of September. Notwithstanding the beauty of his plumage, the vivacity with which he sings, and the ease with which he can be reared and kept, the *Indigo* bird is seldom seen domesticated."

According to Bechstein, the song of this bird resembles considerably that of our common linnet.

The *Lazuli Nonpareil* (*Spiza amoia*) is also a splendid species, which appears to be rather rare, and more limited in its locality than the others. It resembles the *Indigo* bird in size and habits, and is found, during the summer months, along the Arkansas river, near the base of the Rocky Mountains, where it is described to frequent the bushy valleys; keeping

generally in the grass, and seldom alighting on trees or shrubs. The whole head and neck of the male are brilliant verdigris blue; the back brownish black, intermixed with blue; breast ferruginous, becoming pale as we descend; wings variegated with black and blue, with two white bars across; bill and feet horn colour.

Reed Bunting.

Allied to these birds, and connecting them, on the one hand, with the linnets and other typical finches, and, on the other, with the pine bullfinches and crossbills, we have the genus *Erythropsiza*, containing a number of species so similar in plumage, as to be told apart with difficulty, and in which the predominating colour is red, of various shades of hue and brightness. They have a very wide range of geographical distribution, one or two species being found in Africa; but the majority of them inhabit the more northern parts of Europe, Asia and America. We know little of their habits beyond the minute and accurate description which Wilson, the ornithologist of the United States, has furnished us with concerning the only species which he enjoyed opportunities of observing. As described by him, their habits seem intermediate between those of the common linnet and bullfinch of this country.

One species abounds in winter in the United States, *Erythropsiza purpurea*, described by Wilson, under the name of purple finch. "This," he observes, "is a winter bird of passage, coming to us in large flocks, from the north, in September and October; great numbers remaining with us in Pennsylvania during the whole winter, feeding on the seeds of the poplar, button-wood, juniper, cedar, and on those of many rank weeds that flourish in rich bottoms, and along the margin of creeks. When the season is very severe, they proceed to the south, as far at least as Georgia, returning north early in April. They now frequent the elm trees, feeding on the slender but sweet covering of the flowers; and as soon as the cherries put out their blossoms, feed almost exclusively on the stamina of the flowers; afterwards the apple blossoms are attacked in the same manner, and their depredations on these continue till they disappear, which is usually about the tenth or middle of May." Among the *Fringillidæ* of Europe, many feed very much upon

the unopened blossoms of various plants; the goldfinch and linnet for example, on those of the furze, but the common bullfinch (so far as the writer of this has observed), is the only species which attacks and devours the fruit blossoms, and the depredations which two or three of these beautiful birds will commit in a garden in the course of a few days, are by no means inconsiderable. In England we have hardly so destructive a bird in the orchards as the common bullfinch, and the purple finch appears in America to perform the same part which this species does with us. "These birds," Wilson continues, "fly at a considerable height in the air, and their note is a single *chink*. They possess great boldness and spirit, and when caught bite violently, and hang by the bill from your hand, striking with great fury; but they are soon reconciled to confinement, and in a day or two are quite at home. I have kept a pair of these birds upwards of nine months to observe their manners. One was caught in a trap, the other was winged with a gun; both are now as familiar as if brought up from the nest by the hand, and seem to prefer hempseed and cherry blossoms to all other kinds of food. Both male and female, though not crested, are almost constantly in the habit of erecting the feathers of the crown; they appear to be of a tyrannical and domineering disposition, for they nearly killed an indigo bird, and two or three others that were occasionally placed with them; driving them into a corner of the cage, standing on them, and tearing out their feathers, striking them on the head, munching their wings, &c., till I was obliged to interfere; and even if called to, the aggressor would only turn up a malicious eye to me for a moment, and renew his outrage as before. They are a hardy vigorous bird." The males are all over dark crimson, deepest on the head and chin, and lightest on the lower part of the breast; back streaked with a dusky colour, and wings and tail dusky black, the latter considerably forked. The female is of a brown olive, or flaxen colour, streaked with dusky black, and having also a little whitish about the head and under parts.

"A male," says Wilson, "of one of these birds, which I kept for some time, changed in the month of October from red to greenish yellow, but died before it recovered its former colour." There is something very obscure in the changes of hue which most finches exhibit which are tinged more or less with red. Those of the common linnet, and its more immediate congeners, we shall describe presently; in them the red invariably disappears entirely after moulting in the cage, and the approach of the breeding season, though it excites them to song, and, although they breed very readily in confinement, never brightens their plumage, in the least degree, as is the case when they are flying wild. In a state of nature, they push forth dark brownish-red feathers in autumn, which in spring change rather suddenly to bright scarlet; but the purple finch appears in winter to be clad in a garb of bright red, so that the fact of Wilson's bird changing by moulting into "greenish yellow," seems rather to have been an effect produced by the unnatural state of confinement; and it is very probable that it would never afterwards have assumed its red plumage in the cage.

A species closely allied to the purple finch, and which Wilson erroneously supposed to be identical with it, is the *Erythropsiza rosea*, an inhabitant chiefly of northern Europe, but which is also found occasionally in arctic America. Its form and plumage, and,

in all probability, its habits, much resemble those of that bird; and Temminck describes it to frequent the neighbourhood of rivers, particularly in Siberia: in winter it visits the eastern parts of the south of Europe, and is now and then observed in Hungary.

The crimson-crowned finch, *Erythropsiza erythrina*, is another European species, but found chiefly within the arctic circle, it does not, however, appear that it has yet been noticed in America, though the following species, nearly allied to it, is rather plentiful in the district of country extending along the base of the Rocky Mountains.

CRIMSON-NECKED FINCH (*E. frontalis*), has been figured and described in C. L. Bonaparte's continuation of Wilson's work. This bird is only one remove from the pine grosbeak, or as it is termed by some authors the pine bullfinch (*Corythus enucleator*). It so resembles the *E. erythrina*, also, that it requires some acumen to distinguish these apart, at least in the state of stuffed specimens. There are many circumstances, however, which tend to indicate that they are distinct and separate species. All the birds of this genus so nearly resemble each other, that their specific differences are still involved in great confusion, and it is probable they may long continue so, unless we have some better data for determining these separate characters than dry and distorted skins. The four northern kinds, however, which are here mentioned, may be considered as pretty well made out, as also three or four others, of which, however, nothing more is at present known, except the names.

We next come, in a regular series, to the pine bullfinch of authors, a large species inhabiting both continents, and much more closely allied to the last mentioned birds, and to the cross-bills (*Loria*), than to the true bullfinches, with which it has generally been associated. It is, in fact, a true *loria* in all respects, excepting the bill, and undergoes the same very peculiar changes of colour; the young birds, which have once moulted, being clad in a much brighter livery than they ever wear afterwards. Like the crossbills, it is an inhabitant of the northern pine forests, out of which it is hardly ever found; but as it has generally been considered as a bullfinch, from a slight resemblance in the form of the beak, it will be more convenient to describe it along with the true bullfinches, in the general article PYRRHULA. The true bullfinches have the plumage altogether of a different character and texture from this species; and, though considered as the type of a division of the *Fringillidæ*, to which the name *Pyrrhulina* has been given, and in which the crossbills and erythrospizæ are usually placed, they do not appear to have any considerable degree of direct affinity with any of the others.

The crossbills (*loria*) connect the pine bullfinch with the siskin and redpole linnets, to which they are much more nearly allied than would be supposed from a mere casual glance at stuffed specimens. Four species of them are now known, three of which have been met with in the British islands, one as an occasional visitant, in large flocks, and the other two as extremely rare and accidental stragglers. They are very interesting birds, having one of the most singularly constructed bills to be found in the whole feathered creation, and which, though considered by some as a deformity, is in reality one of the most beautiful contrivances, one of the most admirable adaptations of means to end which occur in the whole

range of animated nature. For a more definite account however, of these birds, we must refer to the article LORIA.

Next follow the siskins and goldfinches, and then the canaries, all of which, however, having been already described in the article CARDUELIS, we proceed at once now to the different

LINNETS (*Linaria*). The form and plumage of the common linnet are too well known to require a description. It is one of the commonest of British birds, everywhere frequenting open heaths and commons, and breeding in the furze and other bushes. In autumn they associate in large flocks, and traverse the more cultivated parts of the country, often alighting by thousands where the plough has been at work, in search of the many seeds of various wild plants which are everywhere scattered and distributed; they are sometimes observed in company with other species of *Fringillidæ*, but more commonly in flocks, composed entirely of their own species. They are cheerful and lively birds, and very sweet and pleasing songsters, the most musical indeed of all our finches, excepting, perhaps, the goldfinch, though this is matter of opinion. Great numbers of them are annually captured by the bird-catchers, who take them with clap-nets and call-birds, by which means they are very readily decoyed and made prisoners.

Linnet.

The nest is generally constructed in a furze bush, and is formed of moss and stalks of grass neatly interwoven with wool, and lined with feathers and hair. The eggs are four or five in number, of a bluish white, speckled with purplish red colour. They feed on most of the smaller seeds which come in their way, as those of the flax, hemp, dandelion, thistle, &c., and particularly on those of the cruciform plants; and they eat also the leaves of groundsel, chickweed, and some others.

They are strictly granivorous birds, at no period of their existence subsisting upon insect food, nor will they touch it in captivity if offered to them. Even the young are entirely reared upon macerated vegetable diet ejected from the craws of the old birds, and the same obtains in the sub-genera *Carduelis*, *Coccothraustes*, and *Canaria*; though in the chaffinch, sparrow, and bunting tribes, the young are brought up wholly upon insects; and even the adult birds of these latter divisions will feed on insects whenever they have the opportunity. Authors (in many instances mere compilers one from another), have made strange confusion in describing the common linnet, having confounded the summer plumage of this bird with the

greater redpole; another, and a very differently formed species, and which is apparently unknown to almost every British ornithologist.

The SERIN (*Fringilla-serinus Europæus*) is a curious little finch, a native of the central parts of Europe, and remarkable for its small and very short bill. It is of a beautiful yellow, variegated a little with a darker colour. In winter they are found much about gardens upon the fruit trees, but never along the streams and rivulets like the redpole and siskin. It is a pleasing and most indefatigable songster, its notes being low but very melodious, and somewhat resembling those of the skylark, intermixed with a little of the canary. According to Bechstein, "they sing incessantly, either perched on the outer branches of a tree, or whilst rising in the air, and gently sinking again to the former situation, or whilst flying from tree to tree. Their call resembles that of the canary, and their habits are mostly similar to that species. They feed on all the small seeds found in fields and orchards, particularly groundsel, plantain, garden pimpernel, and others of the same kind. In woods they seem attached to beech and oak-trees.

"The nest," according to the same author, "is generally placed on the lower branches of apple and pear trees, sometimes on beeches and oaks, but never on willows by the water side. It is constructed of fine and divided roots, mosses, lichens, principally of those which are farinaceous, the whole being entwined with great nicety, and lined with a thick bed of feathers, horse-hair, and pig's bristles. They generally lay three or four, rarely five eggs, which are white with spots of bright reddish-brown, which form a zone towards the large end. The hen sits thirteen or fourteen days, during which time the male feeds her. He also helps to feed the young ones, which is done by disgorging the food; the young closely resemble those of the common linnet, and may be reared easily upon soaked rape-seed. They remain grey till after moulting, when they attain their full plumage, but are never so beautiful in the house as in the wild state. After being kept a few years in the cage, the yellow on those taken full grown becomes pale, and fades at length to nearly white. This bird will pair with the canary, siskin, linnet, or goldfinch." It is not found in Britain.

The most typical of all the finches are, perhaps, the grosbeaks (sub-genus *Coccothraustes*), in which the bill is conical, very thick, bulging at the base, and rapidly tapering to a point; each mandible being nearly of equal thickness. The wings, in the more typical species, have the tertiary feathers singularly widened at the tips, and abruptly ending, looking as if their extreme ends had been cut off. They are some of the largest of the *Fringillidæ*, and by the power of their massive horny bill, the larger species are enabled to break the shells of the harder kind of seeds and berries, upon which they principally subsist. Their colours are soft, handsome, and well contrasted, without having any tendency to be gaudy, and altogether they form a very well defined group.

The green grosbeak (*C. chloris*) is a very common bird throughout the greater part of Europe, and is everywhere abundant in the British islands, frequenting hedges and the outskirts of woods. It is of the size of, or rather larger than a sparrow, all over of a dull olive green, brightest upon the rump, throat, and belly, which incline to yellow, and having the outer webs of the primary wing feathers bright yellow; the

wing coverts and tertiaries are in winter broadly margined with ash colour, which gradually wears off towards the breeding season, at which time the green upon the back, and indeed the whole plumage, becomes very much brighter, the terminations of each feather being shed. The female has the green and yellow not so bright, and is altogether of a much browner tint than the male; the young are longitudinally streaked in the manner of the linnet.

This bird is by no means typical of the division of the *Fringillidæ* to which it appertains, being intermediate between the more standard grosbeaks and the linnets and canaries; and is indeed commonly known in many parts of the country by the name *green linnet*. It is also called *greenbird* and *greenfinch*. It is rather a familiar species than otherwise, coming much into gardens, and is seldom found but in the neighbourhood of cultivated ground. Their song is very simple, but subdued and pleasing, perhaps more so from its association, and consists of two or three soft trills, with now and then a very singular note, which may be expressed by *te-c-c-a-a-ar*, pronounced slowly and clearly. In the breeding season this bird often sings on the wing, rising from a tree to a little height in the air, and then fluttering to the next tree in a very curious shuffling manner, as if wounded. The nest is placed generally in some thick hedge, and is composed of moss and wool interwoven with a lining of feathers and hair, and considerably resembles that of the common linnet, but is larger and looser; the eggs are also much like those of a linnet, but are rather larger, bluish-white, speckled (chiefly at the large end), with reddish-brown; about four or five in number, the usual complement in this family.

After breeding, and undergoing the autumnal moult, the green grosbeaks assemble in considerable flocks, which become very numerous about the commencement of severe weather; and they commonly associate with chaffinches and yellow buntings, and sometimes bramblingfinches. They subsist upon all sorts of seeds, and very much upon grain, which latter is never touched by any of the birds we have been hitherto de-

Common Bunting.

scribing; and they appear to feed more upon the green leaves of groundsel and other plants, than any other of our finches. In confinement, when taken young, it becomes remarkably tame; and is often suffered to

fly loose with impunity; it learns the songs of other birds with facility, and has been known to repeat the canary's song very tolerably; one taken old, in the possession of the writer, which has been kept for two or three years in the same cage with several other gregarious birds, now imitates very accurately the notes of a bullfinch, or of his companions. This species breeds readily with the canary.

**HAW GROSBEEK** (*Coccothraustes vulgaris*) is the largest, and one of the most beautiful of the European finches. Its length is about seven inches, of which the tail measures two inches and a third. The bill which is extremely powerful, is like a large blunt cone, very thick in proportion to the size of the body, of a dark bluish colour in summer, in both sexes, and pinkish white, or flesh colour, with the tip blackish, in winter. The forehead, in the male, is yellowish brown; cheeks and crown of the head, light chestnut; beneath the chin, black, forming a large square spot; nape of the neck, a delicate ash grey; back dark rich brown, shaded with grey upon the rump: tail-coverts, light chestnut; under parts of the body dirty red, shading into whitish about the vent; the lesser wing-coverts are black, the greater brown behind and whitish before, which forms a pale streak across the wings; quills black, tipped with steel-blue, their inner webs having a long white spot, secondaries steel-blue, and terminated with angles so obtuse as to appear as if the tips had been cut off; tail black, the tips of the two centre feathers shaded with grey, and all the exterior ones are white at the extremity of the inner web.

Haw Grosbeak.

All over the plumage of this bird is very soft and silky in its nature, more so than in any other of our *Fringillidæ*, not excepting even the goldfinch; and it undergoes no seasonal change, as is the case with all the others, being equally bright in winter and summer, and the edges of the feathers being permanent.

The female has the general tints of the plumage rather duller than the cock bird, and the cheeks, head, and upper tail-coverts are of a greyish chestnut colour. The young, in their nestling plumage, differ from adults considerably, the head and throat having a strong yellowish tinge; there is another bar of whitish across the wing, formed by the lesser coverts, being also tinged with brownish white; the rump is of a brownish cream colour; from each corner of the mouth proceeds downwards a row of small black feathers, which just trace the outline of what in the old bird is a large black spot; and the flanks are thickly dotted with transverse oval brown spots, very similar to those upon the breast of a hen missel-thrush; quill and tail-feathers the same as other adults.

The haw grosbeak is rare in the British islands, and in summer is one of the very shyest birds we have, which has occasioned several writers to speak of it as a winter visitant, though at the same time they were aware of its breeding abundantly in some parts of France; so that, contrary to all analogy or probability, they described it to migrate northward to spend the winter. It is properly a bird of the woods, and even forests, but so very shy, that in some parts of Kent and Surrey, where it is far from being very uncommon, it is extremely difficult to get even a distant view of it, and specimens in summer plumage are only to be obtained by very tedious and patient watching. It is entirely a vegetable feeder, subsisting chiefly on the various produce of different trees, as the kernels and seeds of the beech, elm, ash, and maple; and in winter of the berries, or rather the seeds and stones, of the juniper, service tree, and whitethorn; it attacks also cherries and plums, the stones of which, by means of its powerful beak, it breaks with the greatest ease, to feed upon the enclosed kernels. The writer has known, also, a brood of young ones to feed very largely upon green peas. A wounded old one, which he kept for some time in confinement, rejected almost everything but hempseed, and invariably refused to feed on haws, the berries from which the species has been named, which seems to indicate that they only resort to those in times of necessity. This bird will become extremely familiar in confinement, though it is necessary to guard oneself from its powerful beak, with which it can inflict a very severe bite.

The song of the haw grosbeak is very simple and inward, with but little melody to attract our notice; it consists of a low whistling, intermixed with some harsh tones, and is audible only at a short distance. The nest is well built, but shallow, formed of sticks and lichens, and lined with fibres of roots and other soft materials. This is placed usually on the upper branches of small trees, and often in the thick top of a pine or other evergreen. The eggs are from three to five, greenish grey, spotted with brown, with a few streaks of blackish at the larger end. We knew an instance of one of these nests being taken in the fork of a tree, near Richmond Park, Surrey; and another being placed the following year in the same identical situation. The species is not rare in that neighbourhood, but upon entering a coppice, the very first bird to take the alarm and flee away is generally the haw grosbeak. The only chance of shooting one in summer is the instant they take their flight from a tree, for they are not to be discovered amid the thick foliage. In winter they congregate in small flocks, and frequent the hedges in bad weather, losing much of their usual wariness.

There is a species closely allied to the haw grosbeak which inhabits the Indian islands, and another, a very beautiful one, with black and bright yellow plumage, termed *C. icterina*, in the Himalaya. North America also possesses one species, and a very characteristic *coccothraustes*, which is described by the continuator of Wilson's Ornithology under the name of

**EVENING GROSBEEK** (*C. vespertina*). It is a beautiful bird, about eight and a half inches long; bill greenish yellow; forehead bright yellow, prolonged in a broad stripe over the eyes; head black, shading, as it descends, to olive-brown; back, rump, and under parts, yellow, brightest upon the rump,

and tinged with olive brown upon the belly; quill and tail feathers black, the two exterior of the latter having a large oval black spot; lesser secondary feathers pure white.

This bird appears to have an extensive range over the more northern and north-western parts of America. By day they are described "to retire into deep swamps, which are covered with a thick growth of various trees of the coniferous order, and only leave them in small parties at the approach of night. Their note is strange and peculiar, and it is only in twilight that they are heard crying in a singular strain. This mournful sound, uttered at such an unusual hour, strikes the traveller's ear, but the bird itself is seldom seen; though, probably, from its unacquaintance with man, it is so remarkably tame and fearless, as almost to suffer itself to be caught with the hand\*." The sexes are very much alike.

**CARDINALS** (*Guiracæ*). The other American birds allied to the grosbeaks pertain to a separate division, which is peculiar to the new world, and intermediate between *Coccothraustes* and the bullfinches. In these, the bill is higher than broad, the upper mandible being larger than the lower, and covering its margins entirely, as in the bullfinches; its form is not so completely angular, but is very slightly curved. Red is the predominating colour of the plumage, which in its texture resembles more that of the true bullfinches; and the wings are generally short, and the tail rather long than otherwise. The type of this division is the

**RED CARDINAL** (*G. Cardinalis*), Cardinal Grosbeak, or Virginian Nightingale, as it is sometimes called; a bird, of which caged specimens are often imported into this country, and sold at a high price. This species is eight inches in total length, and eleven in extent of wing; all the upper parts dull dusky red, the crest (which is long, pointed, and erectile), and the whole under parts, bright vermilion; front, cere, and throat, black; tail extending three inches beyond the points of the wings; bill thick and powerful, and of a bright coral hue; legs and feet pale hazel. The female has the crest shorter, and raises it less frequently, and is also of smaller size than the male; all the upper parts are brownish olive, the tail, wings, and tip of the crest excepted, which are nearly as red as in the male; breast and lower parts reddish drab.

"The beautiful song of this species," observes Bechstein, "is so like that of the nightingale, that the name of *Virginia Nightingale* has been given to it; but its voice is so strong, that it pierces the ear. It sings through the whole year, except at the time of moulting." They have only, however, a few of the more powerful and shaking, or thrilling notes, of that bird, at least, to judge by those we have heard singing in cages. Wilson says, "to this name, as Dr. Latham observes, they are fully entitled, from the clearness and variety of their notes, which, both in a wild and domestic state, are very various and musical: many of them resemble the high notes of a fife, and are nearly as loud. They are in song from March to September, beginning at the first appearance of dawn, and repeating a favourite stanza or passage twenty or thirty times successively; sometimes, with little intermission, for a whole morning together, which, like a good story too often repeated,

becomes at length tiresome and insipid. But the sprightly figure and gaudy plumage of the red bird," (as he is commonly called in the United States), "his vivacity, strength of voice, and actual variety of note, and the little expense with which he is kept, will always make him a favourite.

"This species, like the mocking-bird, is more numerous to the east of the great range of the Alleghany Mountains, and inhabits from New England to Carthage. Michaux the younger, son to the celebrated botanist, informed me, that he found this bird numerous at the Bermudas. In Pennsylvania and the northern states, it is rather a scarce species; but through the whole lower parts of the southern states, in the neighbourhood of settlements, I found them much more numerous; their clear and lively notes, in the months of January and February, being, at that time, almost the only music of the season. Along the road sides and fences I found them hovering in half dozens together, associated with snow birds, and various kinds of sparrows. In the northern states they are migratory; but in the lower parts of Pennsylvania they reside during the whole year, frequenting the borders of creeks and rivulets, covered with holly, laurel, and other evergreens. They love also to reside in the vicinity of fields of Indian corn, a grain that constitutes their chief and favourite food. The seeds of apples, cherries, and of many other sorts of fruit, are also eaten by them: and they are accused of destroying bees.

"In the months of March and April, the males have many violent engagements for their favourite females. Early in May, in Pennsylvania, they begin to prepare their nest, which is often fixed in a holly, cedar, or laurel bush. Outwardly, it is constructed of small twigs, tops of dry weeds, and slips of vine bark, and lined with stalks of fine grass. The female lays four eggs, thickly marked all over with touches of brownish olive, on a dull white ground; and they usually raise two broods in a season.

"The opinion which so generally prevails in England, that the music of the groves and woods of America is far superior to that of Europe; I, who have a thousand times listened to both, cannot but admit to be correct. We cannot with fairness draw a comparison between the depth of the forests in America, and the cultivated fields of England; because it is a well known fact, that singing birds seldom frequent the former in any country. But let the latter places be compared with the like situations in the United States, and the superiority of song, I am fully persuaded, would justly belong to the western continent. The few of our song-birds that have visited England, extort admiration from the best judges. 'The notes of the cardinal grosbeak,' says Latham, 'are almost equal to those of the nightingale. Yet these notes, clear and excellent as they are, are far inferior to those of the wood thrush, or even to those of the brown thrush, or thrasher (*Orpheus rufus*). Our inimitable mocking bird is also acknowledged by themselves, to be fully equal to the song of the nightingale, in its whole compass. Yet these are not one-tenth of the number of our singing birds. Could these people be transported to the borders of our woods and settlements in the month of May, about half an hour before sunrise, such a ravishing concert would greet their ear as they have no conception of."

Europeans are now perfectly willing to concede

\* C. L. Bonaparte.

that America produces several very fine song birds, and some which are, perhaps, fully equal to the best of any other country; yet still there is some reason to consider that the above picture is a little overdrawn. Certain it is, that persons from this continent are, in general, much disappointed with the music of the American groves, at least when they expect to find it surpass, or even approach to that which enlivens the woodlands and the fields of Europe. Even the mocking bird, unquestionably the prince of American songsters (as we have heard a sufficiently competent judge in these matters declare), though his own native notes would raise him to the very foremost rank of feathered musicians in any country, for the most part amuses rather by the correctness of his imitations of various discordant sounds, than charms the ear by the harmonious melody of his voice. Wilson himself never heard the nightingale of Europe, nor, from the descriptions he had read of it, was he aware that it sings much more by day than in the night; and he, therefore, institutes a comparison, and contrasts forcibly the music of the mocking bird, which is heard above every other in open day, with the voice of the European Philomel, of which even the bard of Avon says (and Wilson quotes the passage), that

“—if she could sing by day  
When every goose is cackling, would be thought  
No better a musician than the wren.”—

But Shakspeare himself here sacrifices minute accuracy for poetic effect, as all who have lived in neighbourhoods where nightingales pass the summer must be well aware of. Those who are familiar with the European bird, will at once fully recognise the force of the following passage, quoted from Wilson's description of the American mocking bird, and applied to the nightingale of this continent.—“In his native groves, mounted on the top of a tall bush, or half-grown tree, in the dawn of dewy morning, while the woods are already vocal with a multitude of warblers, his admirable song rises pre-eminent over every competitor. The ear can listen to *his* music alone, to which that of all the others is a mere accompaniment.” But we are now wandering much from the proper subjects of this present article, and the merits of the so-called Virginia nightingales have, by degrees, led us to consider those of the “leader of the vernal song” in Europe.

“The males of the cardinal grosbeak,” continues Wilson, “when confined together in a cage, fight violently. On placing a looking-glass before the cage, the gesticulations of the tenant are truly laughable; yet with this he soon becomes so well acquainted, that, in a short time, he takes no notice whatever of it; a pretty good proof that he has discovered the true cause of the appearance to proceed from himself. They are hardy birds, easily kept, sing six or eight months in the year, and are most lively in wet weather. They are generally known by the names, red bird, Virginia red bird, Virginia nightingale, and crested red bird, to distinguish them from another beautiful species, the red pyrange (*Pyrranga rubra*), one of the *Tanagrines*.

“One peculiarity in the female of this species is, that she often sings nearly as well as the male. I do not know whether it be owing to some little jealousy on this score or not, that the male, when both occupy the same cage, very often destroys the female.” Upon the whole, there are several traits here recorded of the red cardinal, which certainly accord very strik-

ingly with the European bullfinch. Their food is the same, each subsisting much on the seeds of various berries, and the plumage of both is of the same peculiar soft texture, unlike that of most other *Fringillidæ*. The female bullfinch sings quite as well as the male, and as to quarrelsomeness in confinement, we have known a female bullfinch to attack and destroy another which was placed for a few minutes only in its cage.

ROSE-BREADED CARDINAL (*G. rosea*), by some writers styled *G. Ludoviciana*, although so far from being common in Louisiana, as the latter name would imply, neither Wilson nor his continuator, C. L. Bonaparte, were able to furnish any instance of its occurring in that territory. Not but that it may occasionally be found there, as the common waxwing sometimes straggles into Bohemia, but it certainly has no more claim to the specific title *Ludoviciana*, than the waxwing has to its common designation of *Bohemian*. If names are to have any meaning at all, surely they are not to convey erroneous impressions; and it is time, now that all such misleading appellations were expunged from our catalogues of objects of natural history, or, at least, that they were retailed only as synonymous till more appropriate designations had come into general use. The rose cardinal appears to be a more northern species than the last, but in winter has been observed in Mexico. Wilson says, “this elegant species is rarely found in the lower parts of Pennsylvania, in the state of New York, and those of New England; it is more frequently observed, particularly in fall, when the berries of the same year are ripe, on the kernels of which it eagerly feeds.—Some of its trivial names would import that it is also an inhabitant of Louisiana, but I have not heard of its being seen in any of the southern states. A gentleman of Middleton, Connecticut, informs me, that he kept one of these birds for some considerable time in a cage, and observed that it frequently sang at night, and all night; that its notes were extremely clear and mellow, and the sweetest of any bird with which he was acquainted.”

“Its recent discovery in Mexico,” observes Bonaparte, “is an interesting fact, and we may safely conclude that this bird migrates extensively according to season, spending the summer in the north, or in the mountains, and breeding there, and in winter retiring southward, or descending into the plains; being, however, by no means common in any known district, or at any season, though, perhaps, more frequent on the borders of Lake Ontario. Its favourite abode is large forests, where it affects the densest and most gloomy retreats. The nest is placed among the thick foliage of trees, and is constructed of twigs outside, and lined with fine grasses within; the female lays four or five white eggs, spotted with brown. This may also be called an ‘evening grosbeak,’ for it sings during the solemn stillness of night, uttering a clear, mellow, and harmonious note.”

This species is eight inches and a half long, and thirteen in extent. The whole upper parts are black, with the exception of the white stripes across the wing; neck, throat, and upper part of the breast, black; lower part of the breast, middle of the belly, and lining of the wings, of a fine lively carmine or rose colour; tail forked, black, with the three outer feathers white at the tips of their inner vanes; bill pure white; legs and feet light blue. These colours are not fully acquired until the second year. The female is rather smaller, with the bill horn colour, instead of white;

the upper parts are of an olive brown, spotted with a darker colour; lines over and under the eye, and all the under parts whitish, with a dark spot along the centre of each feather; tail brown, and not so broadly marked with white. The male, in his first plumage, much resembles the adult female.

The BLUE CARDINAL (*G. carulea*), is another species mentioned in Wilson's work. All the upper parts are of a rich purplish blue, but duller on the back, where it is streaked with a dusky colour; wings black, marked with chestnut colour and blue; tail black and forked, slightly edged with bluish, and sometimes minutely tipped with white; bill of a dusky bluish horn colour; legs and feet lead colour.

According to Wilson, "this solitary and retired species inhabits the warmer parts of America, from Guiana, and probably farther south to Virginia. Mr. Bartram saw it during a summer's residence near Lancaster, Pennsylvania. In the United States, however, it is a scarce species, and having but few notes is rarely observed. Their most common call is a loud *chuck*; and they have also at times a few low sweet-toned notes. They are sometimes kept in cages in Carolina; but seldom sing in confinement." Of a live individual he received from South Carolina, he observes, "during its stay with me, I fed it on Indian corn, which it seemed to prefer, easily breaking with its powerful bill the hardest grain. They also feed on hempseed, millet, and the kernels of several kinds of berries. They are timid birds, watchful, silent, and active, and generally neat in their plumage. Having never yet met with the nest, I am unable at present to describe it."

There are several other species of this genus inhabiting South America, though as nothing peculiar has been related of their habits, it will be hardly worth while here to transcribe their names, or to give a detailed account of their markings. They are for the most part birds of gaudy, or at least showy plumage, and shy and retiring in their habits; generally passable songsters, and subsisting chiefly on the seeds enclosed in berries; and the kernels of the smaller stone fruits. One species, however, we may just notice, as it may often be seen in cages in the London bird shops.

The RED-HEADED CARDINAL (*G. erythrocephala*), or, as it is often called, Paradise Grosbeak, is a Brazilian bird, all over of an ash-colour, except the head (which is adorned with a pointed crest,) and the throat, which are bright crimson. It sings throughout the whole year, but with so weak a voice that the slightest noise overpowers it.

The next group we shall notice are the chaffinches, birds to which the generic name *Fringilla* has by some been more particularly restricted, not, however, as we should say, very judiciously. As a group, the *Fringillidæ* are especially distinguished as seed-eating birds, and many of its forms, as the siskins, linnets, canaries, and true grosbeaks (*Coccothraustes*), are exclusively vegetable feeders, at no period of their existence touching animal food in any shape whatever, even the nestlings being fed entirely with vegetable diet ejected from the craws of the old birds. But this is not the case with the chaffinches, for the adult chaffinch and brambling of this country (the types of the division) subsist much on insects of various kinds, and their young are always brought up wholly upon insects. This is in some degree indicated by their structure; for it will be found,

that those birds which live wholly upon grain require a craw, or considerable dilatation of the gullet, which forms a receptacle in which the food may macerate and soften for some time before it is taken into the stomach; and where this occurs the stomach or gizzard will generally be found smaller and less muscular than in species where the craw is wanting, or comparatively small, as will be observed by comparing the craw and gizzard of a common chaffinch with those of the equally common green grosbeak. In the chaffinch the craw is but very small, and in the brambling it is hardly observable, while the stomachs of both these species are larger than in those birds which live wholly upon grain. The absence of a craw, we believe, in any small bird, indicates the species to be partly, if not wholly insectivorous, and we find nothing of the kind in the *Corvidæ*, or crow family, in the starling family, *Sturnidæ*, or even in the larks, all of which are partly granivorous birds, though subsisting more upon animal food; and the whole of them being arranged by Cuvier, together with the finches, in his *tribe or sub-order Conirostres*, though they would certainly range much more naturally as a separate and equivalent division, which by some has been indicated by the name *Omnivori*, signifying "birds which will eat all that is eatable." There is, however, a more definite character than the absence of craw, by which these birds might be separated from the fringillidous races; we allude to a peculiarity in the plumification. In all the *Corvidæ*, the *Sturnidæ*, and the larks, the young birds shed their whole plumage at the first moult, including the wing and tail primaries, and a few weeks after quitting the nest; but in the *Fringillidæ*, as in all the true *Dentirostres*, although the first clothing feathers are in most cases changed even more early\*, the wing and tail primaries are in no instance that we are aware of shed until the second general autumnal change of plumage, and this holds even in species which, as the pipits and wagtails, moult their clothing-feathers twice in the year, as we can safely assert from repeated and careful observation; so that, curious as it may seem of species which so much resemble as to be popularly (and even scientifically by the older naturalists) arranged together in a single genus, lark, it is nevertheless a certain fact, that, while the true larks (*Alaudæ*) change their wing and tail primaries almost immediately after leaving the nest, the pipits (or, as they are often called, titlarks) do not shed theirs until the third (including the vernal) time that they change their clothing-feathers. We may observe, also, that there are some species, as the swallow tribes and the bearded reed bird, which appear to change the tail-feathers at the first moult, but not the wing primaries. The latter species is indeed more peculiar in its characters than any other bird we know, and will range naturally with no family whatever. It is also the only bird we know of allied to the *Dentirostres* which exhibits a craw, from which it differs strikingly from all the members of that division. To return, however, to the consideration of this character, although its absence appears invariably to indicate that a species is at least partly insectivorous, its presence does not in all instances prove the reverse;

\* In the blackcap, and some other dentirostral birds, the nestling feathers of the breast are changing even before the primaries have attained their full length.

for the sparrows and the buntings, which have large claws, subsist much, and feed their young wholly, upon insects. The true position of the chaffinch genus we consider to be intermediate between the typical finches and the *Spizæ*, or nonpareils, of the American continent.

The shape of the bill is, in the chaffinch genus, conical, longer than deep, straight and pointed, and having the conical edges entire; they are of a longer and more slender form than the grosbeaks, and the bill is less strong and thick, and less swollen at the base, than in those birds. Their habits are also less arboreal, and they obtain their food more upon the ground, where they sometimes hop about, but more generally, when feeding, use a peculiar even walking mode of progression, advancing by quick short steps, as all must have noticed who have observed a common chaffinch feeding on the road. The plumage is, in winter, generally very much fringed with terminal edgings, inasmuch that their colours often appear different at different seasons of the year; but, as they increase in age, they have less and less of these edgings at every moult, as is indeed the case with all other birds the feathers of which are thus tipped.

The common chaffinch (*Fringilla cœlebs* of Linnæus) is a handsome and a gay and sprightly bird, very abundant in most parts of the British islands, and much too well known to require its plumage being described. It is termed *cœlebs*, or the bachelor, from the habit which the females have, in its more northern localities, of migrating in winter a little to the southward, while the males continue about their summer residence all the year. This separation of the sexes is, however, comparatively very partial in the British islands, many female chaffinches remaining throughout the winter, even in the northern parts of Scotland; but it is observed, sometimes, in cold seasons, even in the southern counties of England; and indeed, flocks of hen chaffinches, from the northern parts, may occasionally be seen in the south of England almost every winter, while the majority of resident individuals continue solitary.

The chaffinch has a simple and pleasing song, rendered, however, more so by its associations with early spring, this bird being one of our earliest songsters, and occasionally treating us with a repetition of its short stave, even in autumn. There is no variation in its music, and it consists but of a simple run of notes, reiterated over and over again, till it becomes tiresome. Yet this monotonous stave seems to be admired most unaccountably by our continental neighbours, with whom the chaffinch is one of the commonest and most favourite cage-birds, so much so, that Bechstein, a professed "bird-fancier," devotes no less than seven pages of his work to a dissertation on its song, and five or six more to the mode of capturing it, and manner of treating it in confinement. "To such an extent," he says, "is the passion for this bird carried in Thuringia, and those which sing well are sought for with such avidity, that scarcely a single chaffinch that warbles tolerably can be found in the province. As soon as one arrives from a neighbouring county, whose notes appear good, all the bird-catchers are after it, and do not give up the pursuit till they have secured the prize."

"This bird," he observes, "is so great a favourite in Germany, that not a single tone of its voice has escaped the experienced ears of our bird-fanciers. They have observed its nicest shades, and are con-

tinually endeavouring to improve and perfect it. I confess I am myself one of its warmest admirers. I have constantly around me the best songsters of the species, and, if I liked, could write a good-sized volume on all the details of its music," &c. And he does distinguish, by separate names, as many as eight variations, or simple modifications of its lay.

"In Ruhl," he relates, "a large manufacturing village in Thuringia, the inhabitants, mostly cutlers have such a passion for chaffinches, that some have gone ninety miles from home to take, with bird-lime, one of these birds, distinguished by its song, and have given one of their cows for a fine songster; from which has arisen a common expression among them, that such a chaffinch is worth a cow. A common workman will give a *louis d'or* (sixteen shillings) for a chaffinch he admires, and willingly live on bread and water to gain the money." In England there are very few indeed who think the chaffinch worth keeping in a cage.

This species builds a remarkably beautiful nest, placing it in various situations upon the trees and bushes, sometimes amid the ivy, encircling their trunks, at other times in the forks of smaller branches, and very frequently in old apple-trees, overgrown with lichens and moss. It is formed of different mosses and lichens, closely interwoven with wool, and warmly lined with feathers and hair, in its outward appearance always accordant with the particular situation. The eggs are four or five in number, of a bluish white, tinged more or less with pink, and marked with streaks and spots of purplish red. It is widely dispersed, and found in all parts of Europe.

THE MOUNTAIN CHAFFINCH (*F. montifringilla* of Linnæus) we have already described under the name of BRAMBLE-FINCH. There are other species inhabiting Asia, but perfectly similar, we believe, in their habits to the common chaffinch. Closely allied to them are the different snow finches, which are still less arboreal in habit, and have smaller bills; their colours also are more uniform and less brilliant.

THE ALPINE SNOW-FINCH (*F. nivalis* of Linnæus) is a species very common upon the Alps and Pyrenees, with plumage chiefly ash colour above, and whitish beneath, mottled with black and white; the bill is of a glossy black. This bird and another allied to our common hedgechanter, the *Accentor alpinus*, inhabits higher up the European mountains than any other. It is found in winter as far north as the middle of Germany, where it associates often with the mountain chaffinch, but is even more insectivorous than that species. It sings a great deal, though there is nothing in the quality of its song to recommend it to particular notice. According to Temminck it builds its nest upon the rocks, or in their chinks and crevices, and lays about five eggs of a pale green, with faint lines and spots of ash colour, intermixed with a few spots of dark green. Its food consists of the seeds of the pine and larch, together with various kinds of insects.

THE AMERICAN SNOW-FINCH (*F. hyemales*) came under the observation of the talented ornithologist, Wilson, and accordingly we are furnished by him with a detailed and graphic description of its peculiar manners. "Small and insignificant," he observes, "as this well known species is, it is by far the most numerous, as well as the most extensively disseminated, of all the feathered tribes that visit us from the frozen regions of the north, their migration extending from

the arctic circle, and probably beyond it, to the shores of the Gulf of Mexico, spreading over the whole breadth of the United States, from the Atlantic ocean to Louisiana; how much farther westward I am unable to say. About the 20th of October they make their first appearance in those parts of Pennsylvania east of the Alleghany mountains. At first they are most generally seen on the borders of woods, among the falling and decayed leaves, in loose flocks of thirty or forty together, always taking to the trees when disturbed. As the weather sets in colder, they approach nearer the farm-house and villages; and on the appearance of what is usually called falling weather, assemble in larger flocks, and seem doubly diligent in searching for food. This increased activity is generally a sure prognostic of a storm. When deep snows cover the ground they become almost half domesticated. They collect about the barn, stable, and other out-houses, spread over the yard, and even round the steps of the door, not only in the country and villages, but in the heart of our large cities, crowding around the threshold early in the morning, gleaning up the crumbs, appearing very lively and familiar. They have also recourse at this severe season, when the face of the earth is shut up from them, to the seeds of many kinds of weed that still rise above the snow, in corners of fields, and low sheltered situations, along the borders of creeks and fences, where they associate with several species of sparrows. They are at this time easily caught with almost any kind of trap; are generally fat, and, it is said, excellent eating.

"I cannot but consider this bird as the most numerous of its tribe of any within the United States. From the northern parts of the district of Maine, to the Ogeechee river in Georgia, a distance, by the circuitous route in which I travelled, of more than 1800 miles, I never passed a day, and scarcely a mile, without seeing numbers of these birds, and frequently large flocks of many thousands. Other travellers with whom I conversed, who had come from Lexington, in Kentucky, through Virginia, also declared that they found those birds numerous along the whole road. It should be observed, that the road sides are their favourite haunts, where many rank weeds that grow along the fences furnish them with food, and the road with gravel. In the vicinity of places where they were most numerous, I observed the American kestrel (*Tinnunculus sparverius*), and several others of his tribe, watching their opportunity, or hovering cautiously around, making an occasional sweep among them, and retiring to the bare branches of some old cypress, to feed on their victim. In the month of April, when the weather begins to be warm, they are observed to retreat to the woods, and to prefer the shaded sides of hills and thickets; at which time the males warble out a few very low sweet notes, and are almost perpetually pursuing and fighting with each other. About the 20th of April, they take their leave of our humble regions, and retire to the north, and to the ranges of the Alleghany, to build their nests, and rear their young. In some of these ranges, in the interior of Virginia, and northward about the west branches of the Susquehanna, they breed in great numbers. The nest is fixed on the ground, or among the grass, sometimes several being within a small distance of each other. According to the observations of the gentlemen connected with the Hudson's Bay factory, they arrive there

about the beginning of June, stay a week or two, and proceed farther north to breed. They return to that settlement in the autumn, on their way to the south."

The above very interesting account supplies us with a tolerably precise and definite knowledge of the snow-finches, as a group, and what little we have been able to collect concerning the European species accords exactly with it. They are inhabitants of colder situations, and live more upon the ground than the true chaffinch, and do not, like them, nidificate in trees and bushes; they serve to connect the chaffinches with some of the genera allied to the sparrows, between which and them there is a gradual concatenation of intermediate forms, from the consideration of which we might proceed, by an unbroken series, to the buntings and snowflakes, and thence to many other *Fringillidæ*. The members of this family are indeed so numerous, that it would be a hopeless endeavour to describe them all, and they are so generally similar in their economy, differing only in minor characters, which are important only in furnishing means by which they may be naturally arranged, that the describing many more of the species would become a very tedious repetition, if it has not been so in some degree already. An account of the sparrow races will be found in the article entitled *PASSEB*, and the bunting tribes are described under *EMBERIZA*.

There are, however, a great many tropical species, many of which are adorned with gaudy plumage, and which are imported in considerable numbers into this country; and, though we are altogether strangers to the habits of most of them in a state of nature, it may be as well, before we conclude the article *FRINGILLIDÆ*, just to mention a few of the more conspicuous of them, at least of those which are commonly exposed for sale at the London bird shops.

The Whidah birds, (genus *Vidua* of some naturalists) are an African group, the males of which are remarkable for an astonishing development of plumage in the breeding season. In winter they resemble the other sex, and are not very unlike a common linnæ; but they moult their plumage twice in the year, and the following is a description of the adult male of the commonest species, *V. paradisea*, in his summer garb.

Whidah Finch.

The bill (which is intermediate in character between those of the finches and buntings) is of a lead colour; irides chestnut; the head, chin, front of the neck, back, wings, and tail, glossy black; back of the neck pale orange; breast, thighs, and upper part of the belly white, the lower part black; the two middle tail-feathers

measure fourteen inches, are very broad, and terminate in a long filament; the two that follow are also very broad in the middle, but narrower and more pointed at the end, and also end in a similar long filament; the other side feathers are much shorter, but the two next to those which are elongated are a little diverging, and arch over like the tail of a cock, are glossy, and more brilliant than the others.

This beautiful species, according to Bechstein, comes from Angola, and other parts of Africa, and is particularly common in the kingdom of Whidah, in Guinea, whence it has derived its name. They are lively birds, constantly in motion, always waving their long tails up and down, and often arranging their feathers, and they are very partial to bathing. They are healthy birds in confinement, and require to be kept in a large cage, that their handsome tail should not be injured. They sing a little, and their notes though somewhat melancholy are very agreeable.

THE DOMINICAN WHIDAH (*V. serena*) is a smaller species than the last, rarer, and with a still longer tail. It is sold in London at a very high price, and sings as agreeably as the other. A third species, the shaft-tailed Whidah (*V. regia*) has a tail rather shorter, but is equally beautiful, and is not less admired than the two former.

THE AMANDUVAD (*Fringilla amandeva* of Linnæus) is a beautiful little finch, which is brought to Europe in great numbers by the vessels trading with India. It inhabits Bengal, Java, Malacca, and other countries of tropical Asia, and also Africa, is about four inches long, of which the tail measures one and a third; its bill is short and thick, and of a deep bright red; irides also red; the males are several years before their colours become fixed, and the plumage attains its utmost stage of beauty; the head and under part of the body are then of a fiery red, the upper part of a dark grey, but the feathers having a broad red edge, the latter colour seems to prevail; in the same way the rump appears to be of a brilliant orange, though the extreme tips only of the feathers are of that colour all over; many of the feathers are also terminated with shining white spots, which are largest upon the wings, and which impart a remarkably pretty appearance to the bird. The females are smaller, and not so bright, and from the time the species takes to arrive at its full beauty, it is rarely that in a large cage-full of them one can find two that are exactly alike.

They are remarkably social little birds, and sing very sweetly, their run of notes resembling exceedingly those of our pleasing vernal songster, the willow wren (*Sylvia trochilus*); and what is singular, however many may be confined together in the same cage (and in the London shops we may often see thirty or forty), they never sing together, but in turns, the rest keeping quite silent to listen to the little songster. They are very active, often bowing and spreading their tails like a fan, are fed upon canary seeds, and millet, and will live from six to ten years in confinement.

THE WAXBILL (*Loxia astrilda* of Linnæus) is allied to the last, but has a smaller bill, and exhibits a considerable degree of affinity with the bearded reed bird. It is a little larger than the gold crested regulus, its length being but four inches and a half, of which the tail feathers measure two; the bill is dark red; a band which crosses the eyes, together with the centre of the breast and belly, are red; the remainder of the lower parts are grey and the upper

brown, being everywhere streaked with soft transverse hairs, which become finer as they approach the head; tail pheasant shaped. The waxbill inhabits the Canary islands, Senegal, Angola, the Cape of Good Hope, and may be found even as far as India, whence they are brought in considerable numbers to Europe; they are much admired for their gentle and tame disposition, soft plumage, and elegant shape, and are generally kept, like the amanduvads, about a dozen together in one cage. They are fed on millet, which forms their chief subsistence in their native country, to the damage of the fields which are sown with it. They are said to approach the villages as familiarly as our sparrows, and are readily caught in traps. Their song is hardly worthy of notice.

The wild habits of the tropical *Fringillida* are in general but very little known, and they require to be studied, with a view to the generic classification of the birds, which as yet has hardly been attempted, nor can it be accomplished satisfactorily from a mere examination of their stuffed skins. It will probably, however, be a long time yet before we understand much of the peculiar economy of these interesting and beautifully plumaged tribes.

FRITILLARY is the *Fritillaria imperialis* of Linnæus, a large genus of bulbous flowering plants, chiefly introduced into our flower gardens from Persia and the warmer parts of Europe. They belong to *Tulipaceæ*.

FROG (*Rana*), a genus of *Batrachian* reptiles, the typical genus, and the one from which the name is taken, *Batrachos* being the Greek name for a frog. In the Linnæan system, the genus *Rana* included not only the frogs properly so called, but the *tree frogs* (*Hyla*), and the *toads* (*Bufo*); and Cuvier, as he has done in many other instances, has retained the Linnæan arrangement for the whole genus, or rather family, but has divided it into three sub-genera, answering to those which we have mentioned; agreeably to that arrangement, we shall notice the three, each separately under the common English name, and thus the present article will be restricted to a very short account of the true frogs.

The general physiology and relations to the other parts of the animal kingdom will be found treated at some length in the article *BATRACHIA*, so that it will not be necessary to repeat them here, but merely to give some general hints and short notices of the leading species, the whole number of which is too extensive for the space to which we are restricted, and some of the species are so little known, that nothing very interesting to common readers can be said concerning them.

The general characters of frogs are:—The body thick, and a little compressed, elongated, moist on the surface, covered on the upper part with a few small tubercles, and generally granulated on the under surface, with the exception of that of the thorax which is smooth. On each side of the back, just above the loins, some of the species have an angular fold. The fore feet have four separate toes, or toes without any webs, the thumb being larger than the others, and in the males undergoing a peculiar enlargement at the pairing time. The hind feet are much longer, not much less than the length of the body; and they are five-toed and palmated in all the species. The upper jaw is furnished with a single row of small and finely pointed teeth, and there is also a row of similar teeth across the palate. The tongue is short, thick, and

fleshy, adhering to the sides of the under jaw, but capable of being elevated against the palate, so as completely to close the communication with the nostrils. It will be perceived that this structure of mouth is a simple swallowing one; and that a frog can neither bite nor masticate. This points immediately to the kind of food on which it must subsist, namely, food which it can take into the stomach without any preparation; and in the taking of this food, frogs are of considerable service to man on the land, and not altogether useless in the water. The different species of slugs, which are so very destructive in gardens, and to many culinary and other useful plants, form one principal article of the food of frogs; and, therefore, frogs are deserving of much encouragement, in consequence of the value of their labours; and, while their labours are thus valuable, they themselves harm nothing. They do not burrow in the earth, neither do they eat any vegetable substance so far as is known; and, therefore, while they tend to preserve vegetation in the moist places of the garden, and indeed in all places of it on those damp and dewy nights in which slugs are so mischievous, they are always worth protecting; and not only so, but it is worth while to keep a little pond for their aquatic amusements, nor, perhaps, is it altogether amiss to have a bit of stagnant water in some waste place, in which they may breed; for, though the nuptial songs of the frogs are not the most melodious in the world, there is an association of cheerfulness with their croaking—their song, such as it is, is a song of hope; it tells us that the season of growth and beauty is coming, and in the case of the common frog, it tells this very early in the season.

There is another reason why some attention should be paid to frogs, and that is their value as an article of food. Both the common frog and the green frog, which is specially called the esculent one, are fit for this purpose; and, though there is a prejudice against them in Britain, it is an exceedingly ill-grounded and foolish one. It is even worse than this, because it is a remnant of that ancient political animosity which existed so long between England and France; and which, unfortunately for both nations, kept the nearest and most powerful neighbours, whose best interest it was to be at peace, as they could mutually serve each other at the least expense, in a state of constant war, or, at all events, in a panic of mind always prepared for battle. This part of the prejudice is nearly exploded; and it would be just as well to explode the other part; and as we do not now hate Frenchmen, so neither should we loathe frogs. The hind legs and thighs of the frogs are the only parts which are eaten; because they are the only parts which contain much muscle; and this muscle is firm, white, well-flavoured, and exceedingly nourishing. This is, in fact, the case with the muscle of all esculent reptiles, and it arises from the quantity of gelatine, of a very pure description, which exists in all the parts of them.

Frogs have no trace of ribs in their skeletons; the sternum is formed at the under part of a cartilaginous appendage, and it terminates in a disc under the larynx which is united to the clavicles, while a disc at the other extremity, immediately in front of the belly, is attached to the abdominal muscles only.—The bones of the skull are of a prismatic shape, flattened above, and enlarged posteriorly; all the bones of the skull and face are soldered into one piece.—The head is articulated by two condyles to the ster-

num, so that the head has very little motion on the neck. The sacrum is long, pointed, and compressed, but there is no os coccygis, nor any production bearing the least resemblance to a tail. This is the more curious, because the young of all the species of frogs have tails as their only organs of motion; and one species—the Surinam frog—has this organ so large in proportion to that part which is afterwards to be developed into the perfect frog, that the young was long considered as a kind of fish.

There is something in the muscles of a frog worthy of more attention than it has hitherto received. The principle of animal life in frogs appears to be in a very extraordinary manner obedient to external circumstances; to be much less concentrated upon a peculiar organisation than that of many other vertebrated animals; and to make at least an approach to some of the modifications of *action*, which can be made to take place without the presence of any thing which we can call either animal life or organisation. It was by operating on the muscles of a dead frog, and finding that they were excited to action by peculiar applications of different metals, that galvanism, or humid electricity—electricity by chemical decomposition, was at first discovered; and though the muscles of other animals, even the warm-blooded ones, including those of man among the rest, can be excited by the same kind of action, yet they cannot be so strongly excited by so small a degree of it in proportion; and they do not preserve the capacity of being excited for so long a period after the death of the animal.

There is another circumstance in the life of animals of this family, which is also worthy of attending to, and that is the time that they will live, and the muscular parts—indeed, almost any remaining parts—perform their functions after other parts are taken away. Almost any animal can admit of having one or more of the extremities removed, and still continue to live; but any serious abridgment of the internal parts is in most animals attended by a total suspension of all motion in the remaining muscles. But a frog will not only live but leap about after the head and the greater part of the viscera are removed; and a male frog will continue the operation of fecundating the eggs for a good many hours after his head is cut off. This, and also the circumstance previously mentioned, tend to show that there is some connection between electric action and the action of life in the bodies of animals; and when we bear in mind that the life of animals is always the more easily destroyed the more that it is concentrated upon one perfectly organised system, and the more vigorously that that system requires to act in order to maintain itself in the living state; then, though we cannot see where to draw it, there is a line of distinction somewhere to be drawn, between organisation as a congeries of material substances, and action as giving what we call life to those substances; and that as when we chemically analyse the bodies of animals, we find them made up of the common elements of matter; so when we proceed to the virtual analysis of this connection between the organised body, and the action of life in that body, we feel, though we know not well how to express the feeling, that as the substance of the body is a particular modification of that substance which we can with perfect propriety generalise under the name of *matter*, so the life of the body—the merely animal life—is also a particular modification of that which we can generalise under the name of *action in matter*.

This is a very important consideration in more points of view than one. In the first place it is the analysis by which we must work out the theory of production in all organised beings, whether plants or animals, if ever we are to have any thing like rational science upon this highly interesting subject. In the second place it draws, more clearly than could be drawn by any other means, the line of distinction between matter and mind, and assigns to each the limits of its proper province. This is probably the more important consequence of the two, because even the ablest and best-intentioned of those philosophers who have treated, either of the mind of man as immortal, or of the material creation as demonstrating the being of God, have not been able fully to disentangle themselves from the meshes of materialism.

Frogs are exceedingly numerous; and in their productive powers they are more prolific than any other vertebrated animals, with the exception of fishes. Three or four hundred is a very ordinary year's produce from a single pair; and the number is often as many as a thousand. This extraordinary power of multiplication cannot, upon the general principle of the system of nature, have been given without corresponding uses. In the case of frogs, those uses are two-fold, extending both to what they eat, and what eats them. We have already attended to the first of these, in so far as man is concerned, and also taken some slight notice of the second to the same extent.

This is not, however, the proper view to take of the system of nature, if we are to understand that system aright. We are not to suppose that creation is imperfect until man puts his hand to it; for, though it has a capacity to be turned to his use to as great an extent as he can possibly stretch his knowledge, yet the system is in itself perfect without him; and wild nature goes on without the smallest embarrassment or difficulty in those places which have never been trodden by a human foot. We must, therefore, seek for those uses to which the past productiveness of frog applies, without any particular reference to man and his operations.

Now the number of small molluscous animals which the frogs consume, and of which the productive powers are also very great, and also the numbers of larvæ and other minute beings of the waters which they remove both in their tadpole and their mature state, would be productive of unseemly mischief were it not for the frogs. On the other hand, the frogs themselves supply food for a vast number of other creatures. Birds and fishes eat the eggs while they are in the waters, at that season when there is hardly any other supply. The tadpoles have many enemies; and the full-grown frogs contribute largely to the supply of fishes, of more powerful reptiles, and of many species of those birds which live on the banks of the rivers. The eggs and tadpoles of frogs are also subject to various casualties from the seasons. They are often frozen, at least the eggs are; but whether this destroys the principle of life in them, is not so clearly ascertained. A frog itself can be brought to as low a temperature nearly as that of freezing, without being destroyed; but in the experiments which have been made, we believe that actual freezing has been in all cases fatal. A more certain means of destruction is drought; for, as both humidity and atmospheric action are necessary to the quickening of the eggs, they of course perish if the water in which they have been deposited dries up. So also if the little pools and

runs of water into which the tadpoles distribute themselves are dried up, they, as breathers through water, must perish. We need not add that, for the keeping down of the excess of that on which they feed, for the supply of those animals which feed on them, and for compensating for those chances of destruction, their great fertility is required. Nor must we deem it strange, or at all contrary to the beauty of the system of nature, or the benevolent plan of its Author, that there should be a provision for those reciprocal operations of destroying and being destroyed; for all the tribes of beings must live upon each other; and it is this mutual support that forms the beauty of the system, and which enables it, taken as an entire system, to be self supported, which it could not otherwise be. At a superficial glance, we might deem this mutual destruction; but really it is the perfection of the system, and without it this earth would have required another earth to victual it, that would have required a third, and so on without any end to the succession.—in other words the system of things would have been absurd and impossible. Human society forms no exception to this, for the more that the individuals of that society depend upon one another, the more abundant and the more secure are their enjoyments, and the more are they disposed to cultivate all the kindly charities of life.

We need not describe the appearance of the eggs or spawn of frogs, as it is familiar to every one who walks in the fields in the spring months. It is, however, worth while shortly to advert to the transformation which these animals undergo. When they come out of the egg, they consist of an oval head, having a small mouth with a sort of horny mandibles, and an elongated tail, which bears some resemblance in shape to the posterior part of a fish, and has its principal motions lateral, as is the case with fishes. In this state they breathe by means of gills, not very unlike those of fishes, as they consist of little tufts of fibres fixed to the edges of small cartilaginous arches, and the water passes through the fibres much in the same manner as it does through those of fishes. In this stage of their existence, the cavity of the body extends some way into the tail; and the animal really bears some sort of resemblance to a compound of a reptile and fish. It was a long time before the real state of the case was generally known; and hence the ridiculous stories of the spontaneous generation of frogs, and of showers of them falling from the sky, of which we read in the older authors. But any one who chooses to observe water in which there are tadpoles, and they are so abundant that there are few stagnant pools without them, may see the progress of the transformation. The hind feet are the first to be developed; and they are produced not from the tail, which contains no part of the perfect frog, but from the posterior part of the head, which head in the tadpole state is both head and body, as respects the mature frog. After their first appearance these hind feet grow apace, and during their growth the tail hardly diminishes; but by the time that the feet can act in swimming, it will be found that the tail has changed both its external action and its internal structure. It has become thicker laterally, its fin-like margin has disappeared, and it does not act on the water with that lively motion which it had in the finless tadpole. Internally it has lost its muscular texture, and become a reservoir of a sort of fatty substance, which by some process that we do not very well understand, furnishes

the animal with food during the last stage of its transformation, that is of the final development of the fore feet, the shortening and change of the intestines, the development of the lungs, and the absorption of the gills; during which changes, at least in the very last stages of them, the animal can of course neither breathe nor feed in the water. Thus this curious accumulation of nourishment in the tail bears some slight resemblance to that which is provided for the chicken in the egg; and the moment that the change is completed, the tail is absorbed, the gills are gone, the lungs perfected, and the former tadpole no longer capable of breathing in that element in which it has hitherto lived, leaps out of the water a little frog.—The numbers of them that leave the ponds or streams on such occasions are very great, so many as that in particular cases four or five acres of ground have been observed entirely covered with them. Those migrating myriads are very frequently thinned by birds, or where serpents abound, by those species which frequent moist places, and the banks of rivers. It is probable that those migrations may have given rise to the old stories of showers of frogs; because, whether young or old, frogs are always most active when the air is humid.

After their transformation, they are no longer capable of breathing through the medium of water; and there is a change in the way in which they receive the air. While tadpoles they take in the water and air along with it, by the mouth; but when they acquire their perfect form, they do not use the mouth in breathing, at least in the process of inspiring or taking in air. They do this through the nostrils; and after the cavity of the mouth is filled, they elevate the tongue first, to close the nostrils, and then gradually to occupy the cavity, by which means the air is forced into the cells of the lungs, and when it has performed its office, then it is expelled, not by the action of a diaphragm, but by the simple contraction of the abdominal muscles. This is a slow process; but the system does not require very powerful action; and, when they are sporting in the water, it can be suspended for a limited time.

Frogs in their proper state cannot be considered as inhabitants of the water, though they all resort there more or less, but with different degrees of frequency in the different species. Still they are not found in very dry situations, but in marshy and boggy places, and on the margins of lakes and rivers. They resort to the water for food, which principally consists of aquatic insects, worms, and the very young fry of fishes; they also resort there for the purpose of breeding, and, as it is seen from their gambols in the water, they sometimes resort there for mere amusement.

Frogs, in most of the species at least, are understood to arrive at full maturity in about five years; and to live for about fifteen or twenty; but the latter point of course is not very well understood, and from the enemies to which they are exposed, it is probable that but few of them live out the full number of their years, and die of old age. They are susceptible of some attachment; and there have been instances in which frogs have been rendered so tame as to come when called, and take their food out of the hand of those with whom they had become familiar. We shall now very briefly mention a few of the species.

**THE COMMON FROG.** This species requires little description. It is by far the most abundant in the British islands, the most hardy, and the earliest oreeder. They are found in many, indeed in most

countries, but with some variation of size and colour. Their general colour is a dull brownish red, something resembling the tint of a withered leaf; with a black spot on each side of the head, and produced on the sides of the neck. When their several labours of pairing are completed, they quit the parts in which they have deposited their numerous progeny; and, during the latter part of the spring and the summer, they may be seen hopping about in moist and shady places, especially in moist states of the atmosphere. When the air is very dry, they resort much to the waters, it appearing that they do not feel comfortable if their skins become dry; while they hide themselves in the tall aquatic plants, they are very quick and dexterous in the capture of water-flies, which they watch with keen eye, and spring upon with certainty. When the temperature sinks below a certain degree in the autumn, they all disappear; and it is understood that they take up their abode in the water, in that element in which they are first awakened into life, and in which they spend the first form of their existence, and undergo their transformations. This, if not absolutely demonstrated in all cases, as in the nature of things it cannot be, is yet very likely, and very agreeable to the analogy. They neither feed nor breathe during this period of the year; and as the peculiar texture and secretion of their skins protect them as completely from the action of the water as if they were fishes, they enjoy a much more uniform temperature, and, in cold weather, a warmer one than they would do in holes of the earth. It is not a little curious that animals which cannot be produced or come to their ultimate form but in the water, should resort there in order to bring forward their eggs or spawn; and yet this is in accordance with the general analogy. The young are, for some time after they come into life, to be fishes in their element, and in the more important purposes of life; and, perhaps, one might naturally expect that the eggs from which those young are to be produced, should have some resemblance in the mode of their maturing to the spawn of fishes. It has sometimes been said that at the time when frogs betake themselves to the water for the purpose of hibernating, their mouths grow together, by the one lip forming a complete adhesion to the other. This, however, is not the case, and it is not necessary. The mouth of a frog is not, as we have observed, used in the breathing of the animal, but serves merely as a prehensile apparatus in the capture of the food; and when not used for that purpose, it closes not only water-tight but air-tight. When the animal ceases to eat, it has no occasion to open the mouth; and that of course remains closed. It does not appear that they feed in the spring before the time of pairing; and thus they come out of their hibernating places, with the spawn or eggs fully matured, and ready to be excluded and fecundated, nor do they quit the waters, or eat, or move, until that operation is fully performed; and they are absolved from all family cares, quit the breeding waters, and leap about until the close of another season shall send them anew to their hibernating places, to perform the same operations. The common frog is the most prolific of all the British species; and its tadpoles afford an abundant supply of food to various species of birds which breed in the marshes.

**THE GREEN OR ESCULENT FROG (*R. esculenta*).—**This is not the only esculent species, for the common frog is equally palatable and wholesome, though it

does not contain quite so much muscle on the hind legs. It is not nearly so abundant in Britain as the common one. It is of a more handsome form, and more finely coloured. The muzzle is pointed; the posterior part of the body narrow, and the spine at that part arched. The upper part is green, marked with three longitudinal lines, the one on the middle of the back, forming a furrow, and the two lateral ones elevated ridges or margins. These lines are distinct and of a yellow colour; the upper part of the body is whitish, marked with blackish spots.

This species is far more abundant in France than in Britain; and in the vicinity of Paris, and in many other parts of the country, it is the common frog of ordinary parlance. It is a very active animal, and as is indeed the case with all frogs, it swims in the same way that man does, giving the most powerful stroke with the hind legs, but keeping stroke with the fore ones also. It is also an adroit leaper, and will leap to a very considerable height, and catch a fly or other winged insect with great accuracy. The very warm weather is mentioned as the time when it is in the most active state; and it can bear the strength of the sun on the warmest days of summer. It then takes post among the aquatic herbage on the margins of the pools and streams, and sits watching for its prey, with its head immovable, its legs prepared for the leap, and its eye intently looking out, and undazzled by the most powerful heat of the sun. When a fly comes within the range of its powers, which it appears to be capable of estimating with very great exactness, it darts with the speed of an arrow, and very seldom misses its object. Without reference to the estimation in which it is held by the continental gourmands, the edible frog is far from being an uninteresting reptile; but as it has no value for the larder in Britain, it is not studied or appreciated to the extent which, in a natural history point of view alone, it seems to deserve.

**NATTER-JACK FROG** (*R. rubeta*). This is also a British species, though understood to be more rare and local than the esculent frog; but, for the reason mentioned in noticing that one, it is probably much more abundant than is generally supposed. It differs in its habits from the other two British frogs, being found chiefly on the heaths and commons which are comparatively dry, with only occasional pools and bushes. It is to be found on most commons of this description south of the Thames, and also in some parts of the midland counties. It is covered with small punctured tubercles, which give it something the appearance of a toad. It is much more broad and blunt posteriorly than the other frogs, and its hind legs are shorter, feebler, and much less supplied with muscle. Its gait is peculiar, not being either the leaping of a frog or the crawling of a toad, but something intermediate between the two, a lumbering and unseemly sort of walk, by which, and by its tuberculated skin, it is easily known. The colour on the upper part is yellow, marbled with brown, and there is a tolerably well-defined yellow line down the middle of the back. It is an obscure-living reptile, and not often seen, so that little or nothing is known of its manners.

**THE DOTTED FROG** (*R. punctata*) is ash-coloured on the upper part with small green dots. The feet are marked by transverse bands, and the toes of the hind feet are webbed for only part of their length. It has been observed in the neighbourhood of Paris,

and in some other parts of France, but it is as rare there, and its manners are as little known, as the natter-jack in England. The species which have been seen are very small, not exceeding one inch in length; but whether it attains a larger size than this is not known.

**THE PLAITED FROG** (*R. plicata*). This is also a small species, about the same size as the dotted frog. It is a native of the warmer parts of France, and probably of the north of Europe generally. It gets its trivial name of plaited from having two transversely oblique plaits or folds upon each plane. Its colours are, brown on the upper part, and grey on the under. The toes of its fore-feet are entirely free, and those of the hind feet are only half webbed. Those semi-palmated frogs indicate a much less aquatic habit than those which have the toes completely webbed.

**ALPINE FROG** (*R. Alpina*). So little is known of the species which has been described under this name, that it is not very easy to decide whether it be really a distinct species, or only a coloured variety of the common frog. This is the more puzzling, that, in the mountainous parts of this country, the frogs are small and very dark in the colour. The writer of this article has often seen them in the Highlands of Scotland, but did not at the time examine if they had any characters specifically different from those of the common frog. The Alpine frog is described by Laurenti as being wholly black, and as being found only in the mountain of Schneeberg, in Austria, a mountain which is famed for the richness of its botany.

These are the principal species of European frogs that have been noticed and described; but the probability is, that there are many more species; for here, as in the case of the whole class of reptiles, the information which we possess bears no proportion whatever to the extent of the subject. In the case of the extra-European frogs, it is, as might be expected, still worse. Many species have no doubt been named, but little is known of them, and our limits will permit us to mention only a few.

**SURINAM FROG, OR JACKIE** (*R. paradoxa*). In the tales of describers of animals, this is one of the most notorious, if not celebrated, of all the foreign frogs. The trivial name *paradoxa* is absurdly applied, and should be discarded, were it not that it is a memorial of the credulous folly of former naturalists, and may be a beacon to their successors. There is no "paradox" about this frog, or indeed about any animal, for all are equally well adapted to the purposes which they answer in nature, and the paradox is the sole property of the ignorant describer. Hence it were advisable that the paradoxes of naturalists should be treated in the same manner as the paradoxes of the Vicar of Wakefield. "The world said nothing at all about my paradoxes," said the simple-hearted Vicar; and truly it were wise, that not the public only, but the naturalists themselves, said nothing at all about their paradoxes.

The paradox, while it remained one, was this: Other frogs are tadpoles, which have something of the fish about them, and these tadpoles turn to frogs; but in the case of the Surinam frogs the order of things was completely reversed. The story was, that this creature, after having been once a frog, afterwards turned to a fish; that the fish was much larger than the frog, and that it was eaten by the natives under the name of "Jackie," or the frog-fish.

By what sort of metamorphosis it first became a frog, they did not state, and in all probability they never inquired. They saw the frog, and they saw the fish, as they considered it to be. The fish was very considerably larger than the frog, and that a large animal should grow small was the paradox; and as they could not go this length in their simple belief, they believed in something a good deal more paradoxical, namely, that in this frog the process of nature is reversed, and that it is frog first, and larva or tadpole afterwards. Such a reversal of the order of nature would have been truly marvellous, because there is nothing analogous to it, throughout the whole system, in any member of any class of that system which undergoes transformation, and change of element and breathing apparatus. Many creatures breathe through the medium of water when they are in their first or larva state, and afterwards, when they undergo their changes, and arrive at their perfect or final form, the only form under which they are capable of propagating their species, and which they are to retain till they die, become breathers of the free atmosphere. This is the case with all the frogs, and indeed with all batrachian reptiles; and the story of a frog turning into a fish was about as ridiculous as that of the binnacle shell turning into a wild goose, which was so gravely believed, that learned men set it down in print that they had actually seen the process going on in some duck-pond or other in England, where a binnacle, which is entirely a production of the sea, could not by possibility exist. Now, the Surinam frog is just as guiltless of becoming a fish, as those curious mollusca, which bear their shells at the end of long peduncles, which are fastened to a rock, or, in preference to floating wood, a ship's bottom, or anything else, are of changing to geese, though the reporters in both cases stand in some jeopardy of at least a metaphorical transformation of this kind.

This story, like the former, and many others equally absurd, passed current in the books down to about the year 1816, when Mr. W. M. Ireland studied the frog through its change from the rudimental tadpole to the perfect reptile; and Sir Everard Home gave some demonstrations, aided no doubt by the scalpel, the microscope, and the pencil of the highly-talented and most indefatigable Francis Bauer, of the internal structure of the tadpole in two different stages of its growth. The actual observations by Mr. Ireland might have been enough to set completely at rest a question upon which rational men could have but one opinion; but still, as it is difficult to drive the nail of conviction into some heads without the hammer of heavy authority, it was as well that Mr. Ireland's clear and satisfactory account was fortified by the demonstrations of Sir Everard. The following is the substance of Mr. Ireland's communication, which was published in Brande's Journal for 1816:—When first seen by Mr. Ireland, the tadpole was about four inches and a half long by about an inch broad; had a large head and small mouth, very much resembling those of a fish, though the rudiments of two legs were evident just behind the head. In about a fortnight the length of the animal had increased to eight inches, and its breadth to about two and a half; and the rudiments of the legs were developed into nearly perfect members, with five-clawed toes, united by a membrane, evidently the future hind legs of the animal.

On examining its internal structure during this fortnight, the intestinal canal appeared very long and

coiled up, and the rudiments of the lungs were seen in the posterior part of the belly.

Tadpole of the Surinam Frog, a quarter its length.

In about three weeks the fore legs made their appearance, the head and mouth assumed their ordinary figure, the former being considerably smaller, and the latter larger than before; and the animal, which till now had lain at the bottom of the vessel in a torpid state, became more active and lively, and usually remained suspended in the water, with its mouth above the surface. By this time the intestinal canal was wonderfully altered in extent and appearance, being contracted apparently to less than half its length, and having but very few short convolutions, and nearly the whole of the cavity of the belly was filled with fat.

Surinam Frog, nearly full-grown, one half of real length.

In about six weeks the animal was greatly contracted in size, being little more than three inches long by about an inch in breadth, and had become a perfect frog, except some small remains of the tail, which had been gradually sloughing off or absorbed, and the disappearance of which had so greatly contracted the animal's length.

**THE BULL-FROG (*R. pipiens*).** This is a very large species, by much the largest of the genus, measuring not less than eighteen inches from the muzzle to the extremities of the hind feet. The upper part is dull green, mottled with black, and the under part whitish grey, with black spots. There is a copper-coloured circle on each side of the head, which surrounds the tympanum, and points out the place of the ear. It usually posts itself at the mouth of its hole, by the side of the water. It is difficult to take, being very agile, and capable of leaping to the distance of ten or twelve feet at one bound. It is also very voracious, feeding chiefly upon fish, though it is also accused of swallowing ducklings, and even goslings, in their very young state. The real bull-frog does not appear to be very common, as not more than a single pair usually occurs in the same pool or patch of marshy ground. Cuvier is of opinion that various species of frogs are confounded under the general name of bull-frogs in the United States, where these reptiles are of great annoyance to those who reside near marshy places, which places are by no means of rare occurrence in America. The common name of bull-frog is given from the resemblance which the croaking of this species bears to the bellowing of bulls. It is equally loud, if not louder; and as it is carried on incessantly during the night, sleep is out of the question with the stranger who first takes up his quarters in the neighbourhood of the bull-frogs' haunts.

**THE PITPIT-FROG** (*R. halecina*). Rather smaller than the former; green above, with brown spots, and yellow dots in the centre. This species has been confounded with the bull-frog; but, besides the difference in colour, it is much longer in proportion to the thickness, and still more agile, being capable of leaping fifteen or eighteen feet at one bound. It is very common in the marshy places of the southern states of America, and its noise is even more disagreeable than that of the bull-frog properly so called. This, however, is one of the bull-frogs of America.

**EYE-SPOTTED FROG** (*R. ocellata*). This is a very large species, and inhabits to the southward of the former one, as that appears to do of the common bull-frog. It has been found in Guiana as well as in those parts of North America which border on the Gulf of Mexico, and which are remarkable for the abundance of aquatic reptiles of all kinds. Its general colour, on the upper part, is brown, and that on the under part white; and there are very distinct eye-spots on the flanks and sides.

**GRUNTING FROG** (*R. grunniens*). This species is very nearly equal in size to the bull-frog. Its colours are a mixture of brown and bluish and reddish, with yellow spots in the rear of the eyes. It is found in the Floridas, and also in shady places of the West Indian islands, where it is vulgarly called a toad. It seldom comes abroad except during the night. The country people, in some of the islands, are said to rear this species in a domestic state, and they find its flesh very nourishing. It is very active in the rainy season, and can jump over an inclosure five feet in height; but during the dry season it becomes inert, and passes its time in a sort of hybernation; thus affording evidence that the dry season, notwithstanding its excessive heat, is the real winter in tropical climates.

**THE NOISY FROG** (*R. clamitans*). This species has been found in the marshes of Carolina, not far from Charleston. In form it approaches the common frog of Europe, and its length is not above two inches. Its colour is dull ash, irregularly spotted with small black points; and, notwithstanding its comparatively minute size, the din which it makes is said to be more intolerable than that of even the larger frogs.

Such is at least a specimen of the foreign frogs, but it comprises only a very small portion of the number. The Surinam frogs and the bull-frogs are, however, the most renowned, the former for their fabulous history, and the latter for their intolerable noise, in the practice of which they actually drown the belching of the night herons, the hissing of the serpents, the yelping of the prairie dogs, and the whole concert of villainous sounds which vex the ear of night in the wilds of America. There are several species in South America, in the south of Asia, in the Oriental Isles, and in short, in every part of the world; and it should seem that these foreigners are, generally speaking, more noisy than the natives of Europe. It is said, that one brought from the Mauritius to Paris serenaded in so strong and harsh a key, as to drive the evening promenaders from the whole Champ de Mars, so that they were under the necessity of putting a summary stop to his music.

We shall not enlarge more upon this exceedingly numerous, and by no means unvaluable genus of reptiles; but we may have occasion to notice a little more of the duties which the batrachia have to perform in the general economy of nature, when we come

to notice the other two genera or sub-genera, which we propose to do under the titles TREE-FROG and TOAD, in their proper order in the alphabet.

**FROG-HOPPER**, or CUCKOO SPIT-INSECT. The small insect known under the systematic name of *Cercopis spumaria*. See the article CERCOPIDÆ.

**FROG ORCHIS** is the *Gymnadenia viridis* of Richard, a common British plant found in damp meadows. It is the *Satyrum viride* of Linnæus.

**FUCHSIA** (Linnæus). A genus of beautiful flowering shrubs, natives chiefly of South America. Class and order *Octandria Monogynia*, and natural order *Onograriæ*. Generic character: calyx tubular and coloured, the limb five-cleft; petals fixed to the throat of the calyx, connivent, and convolute; stamens included, joined in a double series to the tube of the calyx, or protruding alternately short and longer; anthers oval and erect; pollen glutinous and triangular; style filiform; style headed or four-cleft; berry four-celled, four-valved, and many seeded. This is one of our most common greenhouse plants, and will stand in the open air if defended from frost. It is easy of propagation by cuttings, and deservedly a great favourite. There are nearly a score of different species and varieties of it in our collections.

**FULGORIDÆ** (Leach). A family of hemipterous insects belonging to the sub-order *Homoptera*, Latreille, and to the division *Cicadariæ*, being destitute of organs for producing a sound, having the antennæ inserted beneath the eyes, only three-jointed, terminated by a long slender bristle; two ocelli or none; legs formed for leaping, and the front of the head produced into a kind of snout, variable in size and form in the various species. Here belong the genera *Fulgora*, *Otiocerus*, *Lystra*, *Cixius*, *Pæcilopectera*, *Issus*, *Anotia*, *Asiraca*, *Delphax* (which see), *Derbe*, and several other genera recently established upon structural characters.

Of the habits of these insects but little is known, they are herbivorous in all their states, sucking the juices of plants by means of their long-jointed proboscis, which is ordinarily concealed, laying along the breast. In the typical genus *Fulgora*, are placed the largest species of the family, having the ocelli distinct, and two in number; the antennæ are destitute of appendages, and the front of the head is produced into a large hollow snout-like proboscis, respecting which great differences have prevailed amongst naturalists; this part of the body being generally considered as emitting a very bright light, whence the insects have derived the name of lantern flies. And it is said, that the luminous matter is diffused through the hollow semitransparent projection of the head. Of these

*Fulgora laternaria*.

the Chinese *Fulgora candelaria*, and the South American *F. laternaria* are the more conspicuous. If this be the case, it must be evident from the large

size of the insects, which measure several inches across the wings, that the light must be very distinct, and that the appearance of the trees studded with these living lights must be exceedingly beautiful. The chief testimony in favour of the existence of this luminosity is Madame Merian, who tells us that the Indians had brought her several of the *Fulgore laternaria*, which, by day-light, exhibited no extraordinary appearance, and she inclosed them in a box until she should have an opportunity of drawing them, placing it upon a table in her lodging-room. In the middle of the night the confined insects made such a noise as to awaken her, and she opened the box, the inside of which, to her great astonishment, appeared all in a blaze; and in her fright letting it fall, she was not less surprised to see each of the insects apparently on fire. She soon, however, divined the cause of this unexpected phenomenon, and removed her brilliant guests to their place of confinement. She asserted that the light of one of these *Fulgore* was sufficiently bright to read a newspaper by; and though the tale of her having drawn one of these insects by its own light is without foundation, she, doubtless, might have done so if she had chosen.

Notwithstanding this positive statement, it is to be observed, that from the accounts of some recent observers, there is great reason to distrust its correctness—no one author or traveller having distinctly asserted that these insects are in the least luminous; whilst several, as M. Lacordaire, M. Richard, and Dr. Hancock, who have seen these insects alive, have not observed them to be luminous. One species of this genus, of small size, the *Fulgore Europæa*, is reputed to be an inhabitant of this country.

**FULICA**—Coot. A genus of birds belonging to Cuvier's sub-order *Macrodactyles*, or long-toed birds; and as a Linnean genus including the *GALLINULES* and the *SULTANA-HEN*, under which names we shall notice these birds; and thus we shall be enabled to restrict our present notice to the coots properly so called.

With this restriction the generic characters are given as follows:—The bill middle-sized, strong, conical, straight, compressed, much deeper than broad at the base, the ridge projecting in front, and dilated into a naked plate; both mandibles of the same length, the upper slightly curved and widened at the base, the lower forming an angle; nostrils lateral in the middle of the bill, longitudinally cleft, half closed by a membrane, and pervious; legs long, slender, naked above the knee, all the toes very long, connected at their base, and furnished along their sides with scalloped membranes; wings middle-sized. The coots are more decided residents in the water than even the gallinules, being rarely seen on land, living and travelling in the liquid element, and swimming and diving with equal facility. But they inhabit fresh waters, gulfs, and bays, and venture not into the deep and open seas. Although individuals of the same species vary considerably in dimensions, the sexes are with difficulty distinguished, and in appearance the young differ very little from the adults. Their food chiefly consists of aquatic vegetables and insects.

**COMMON COOT** (*F. atra*). This is a general resident in the old continent, and also in America; and it remains in the British islands the whole year without migrating. The size is nearly the same as that of a common fowl, the average length being eighteen

inches, and the spread of the wings about twenty-eight. The weight varies from a pound and a half to two pounds, according to the condition of the bird. It breeds early in the spring, the female generally constructing her nest of a large quantity of coarse dry herbage, as flags and rushes, well matted together, and bound with softer and finer grasses, in a bush of rushes, surrounded by the water. By heaping the materials together, she raises the fabric sufficiently above the water to prevent the eggs from getting wet; but as this sort of structure very often renders it too conspicuous to the buzzard, and other birds of prey, the old females, instructed by experience, place it on the banks of the streams, and among the tallest flags, where it is much better hidden from the view. It being kept in a buoyant state, a sudden flood, attended by a gale of wind, has been known to drive it from its moorings, and to float it from one side of a large piece of water to the other, with the bird still sitting on it. The female lays from twelve to twenty-one eggs at a time, and mostly hatches twice in a season. The eggs are about the size of those of a pullets, and of a pale brownish white, sprinkled with numerous dark spots, which run into blotches at the thicker end. These eggs are sold in Holland, before they are sat upon, and fetch a considerable price in the market. The incubation lasts twenty-two or twenty-three days. The young soon after quitting the shell dive and plunge into the water swimming about with great ease, and, though they do not return to the nest, nor take shelter under their mother's wings, they still for some time gather about her, skulking under the flags. At first they are covered with a sooty down, and are of a shapeless appearance; and before they have learned to shun their enemies, they are frequently sacrificed to the rapacity of the pike, the moor buzzard, the kite, and other birds of prey. In the isle of Sheppy this species breeds very abundantly, and the inhabitants will not suffer their eggs to be taken, as the bird forms a considerable article of food. On meagre days they are eaten by the French; but, though skinned before dressing, they are not very palatable to every appetite. The common coot is a very poor traveller, and waddles with much apparent difficulty from one pool to another, with an awkward gait. It usually lies concealed among the water plants during the day time, rarely venturing abroad except in the dark, or at night in quest of herbage, seeds, insects, or fishes, the light very probably dazzling its imperfect vision. It can seldom be forced from its retreat by the sportsman and his dog, and rather than spring up it will bury itself in the mud, or if compelled to rise from being very closely pursued, it rises with much fluttering and apparent difficulty. As the foot of the coot has sometimes been described, by those who do not take into account the functions which an organ has to perform along with the shape of that organ, we shall quote a passage from Mudie's Feathered Tribes, as illustrative of the action of the coot's foot. "The legs," says Mr. Mudie, "are placed farther backwards than in any of the birds that live chiefly on land, but they did not appear to be farther back than they are in reality, from the degree to which the tarsal joint is extended when the bird walks."

"It has been said, and the saying has no doubt been founded on that very bending of the tarsal joint, and the tendency that the toes have to collapse the instant that the foot is off the ground, that the coot

walks with great labour and difficulty. But the foot of the coot is another of those instances, of which there are not a few in the structure of birds, in which the very master-pieces (so to speak) of nature's mechanics are considered clumsy, for no other reason than because we will not examine them, and find out why they are thus constructed. The coot's foot has a compound function to perform, and therefore it must be a compound instrument. We look at it only in one of its uses, or rather we look merely at its form, (for when used either way it is used cleverly), and hence we draw the conclusion—from our own ignorance. In order that the coot may properly fill that place which appears to be assigned to it in the economy of nature, it must swim, and also walk, and even climb a tree upon emergency; and though it is not launched upon the broad waters like those pelagic swimmers that fish, or capable of procuring its food by the touch of a dabbling bill like the swimmers in the shallows, it must swim to considerable distances, and with some rapidity. In order to do that, it must have the centre of gravity considerably in front of the articulation of the legs, so that these may act in the wake of the body, and have the advantage of the eddy. It must also swim clean, and without those projecting feathers which are found on the sides of the gallinule, and which, though they assist in making it buoyant when moving slowly, would either impede a quick motion, or be flattened to the sides, and have their buoyancy destroyed by it. The form of the body, the position of the legs, and the extent of the toes, with their lobed margins, answer these purposes remarkably well, and the coot is a very efficient swimming bird. But, again, the coot has to walk, and so that is a lifting motion, while swimming is merely a pushing along, the weight being supported by the water, some modification is required. The swimming foot is converted into a very efficient walking foot, by that very bending of the tarsal joint which, to us, makes the leg appear so awkward. The bending of that joint, without any muscular effort, pulls the tendons that compress the toes, and slackens those that resist that compression because the former tendon passes over the outside of the bend at the tarsal joint, and the latter along the inside. The toes are very long; and the tendons pull them to their extremities, so that the centre of support in the foot is thrown far before the articulation of the tarsal, and by the action of the same spring the weight of the body, is, at every step, discharged from and received by the points of the toes, which it could not be, if the tarsal joints were not bent. The toes being free, too, and not joined by a continuous web, enables the spring of each to act to the full range of its articulations, and the foot to adapt itself to any form of surface upon which the bird may have occasion to walk. Even the produced hind toe has its uses in throwing the foot upwards, and also in walking upon grassy and other elastic surfaces."

The foreign species of coot which have been enumerated by various authors, differ but little from the common coot excepting in size. That of Java is very similar to the European. But the Indian one mentioned by Colonel Sykes, merits notice in the terms in which the colonel himself describes it. It "differs only from the Javanese specimens in being larger, and a shade lighter below." Much larger than the common coot of Europe, but with the same coloured irides (crimson), and does not otherwise differ. Length

inclusive of tail eighteen to nineteen inches: tail two inches. It has the habits of *Podiceps* (Grebes) and, with the gizzard, long cæca, and general internal organisation of a duck, seems to belong to the order *Natatores* (swimming birds). Water weeds and coarse sand found in the stomach."

The only species which Cuvier admits in the Regne Animal as different from the European, is the crested coot of Madagascar (*F. cristata*). It is all over of a bluish black colour; bill white, but red at the base; frontal plate red, rising up and forming a crest; feet black; and length about seventeen or eighteen inches. The habits quite unknown.

**FUMARIACEÆ.** A natural order containing six or seven genera, and many species. The plants associated by their general similitude to *Fumaria*, to form

*Fumaria lutea.*

this type, are non-lactescens herbs, with sometimes tuberous roots, and brittle glabrous stems. The leaves are usually alternate, compound, sometimes cirrhose, and destitute of stipules. The inflorescence is racemose, the pedicels furnished with bractæ, and the flowers irregular and united. The calyx is free, small, and membranaceous, and formed of two sepals which are deciduous. The petals are four, set crosswise, deciduous, either discrete or coalescent by their claws, the two external ones alternate with the sepals, and either one or both saccate at the base; the two inner ones alternate with the outer, hardish at the tops, where they are coloured by a terminal spot, and connected so as to enclose the anthers and stigma. The stamens are six in number, the filaments diadelphous, united into two bundles, which alternate with the two inner petals, and are therefore opposite the outer ones. The anthers are six, the lateral in each bundle being one-celled, while the central ones are each two-celled. They are small, erect, and open longitudinally. The germen is formed of two connate seed-vessels, the style filiform, and the stigma two-plated and parallel with the internal petals.

The *Fumariaceæ* are innocuous plants, inodorous, herbage bitter, and which has been esteemed slightly diaphoretic and aperient. *F. officinalis* is the *Fumus terreæ* of the older herbalists, so called from the light and smoke-like cloudiness of its foliage, whence the modern generic name *Fumaria*. *Corydalis bulbosa*, which has thick roots abounding in fœcula, is resorted to by the Kalmucs in winter as food.

**FUNGI.** This extensive collection of plants forms the ninth order of the class *Aphyllæ*, belonging to the grand division *Cellulares*. It contains all the mushrooms, mildews, &c., found on decayed vegetable or animal matter. Many doubts have been entertained of the exact nature of these plants, some believing them not vegetable but animal productions, while others have denied that they are either, but some fortuitous effects of nature. But all these speculations have been shown to be based on error, and no one now denies that fungi are truly plants.

Fungi and insects have not inaptly been called "the scavengers of nature," for both labour, and with astonishing effect, in the removal of refuse matters, which, were they left on the surface of the earth, would be found not only useless incumbrances, but injurious tenants. The fungi are for the most part parasitic plants, and chiefly grow on dead or decaying substances. These they help to disintegrate and dissolve, and speedily remove, converting the exuvie of one generation into manure and vegetable mould for the support and sustenance of the next. For these duties, their minute seeds and wandering habits particularly suit them. See *MUCOR*, *MUSHROOM*, &c.

**FUNKIA** (Sprengel). A genus of hardy perennial herbs, natives of China and Japan, introduced in 1794, under the name of *Hemerocallis*, but separated therefrom by Sprengel. Generic character: corolla bell-shaped, swollen at the base, contracted above the germen, limb in six divisions, somewhat gaping; stamens filaments inserted into the bottom of the tube declining; anthers incumbent; style declining; stigma obtuse; capsule three-celled, many seeded. Propagated by division.

**FURCRCEA** (Ventenat). A genus of tropical perennials allied to the *Agaves*, being succulent and treated as aloes usually are. They belong to the natural order *Bromeliaceæ*.

**FURZE** is the *Ulex Europæa* of Linnæus, a well known plant inhabiting waste ground and commons. It is extensively cultivated in some places where the land is poor, and cut every second or third year and made into faggots for the use of lime and brick kilns. It is also used as fodder for horses, being mown when very young, and bruised in a mill to soften its spines. Although its principal flowering season be in May and June, it flowers at every other season, it being a rare thing to see a patch of a dozen plants without some one or other of them being in flower.

**FUSUS** (Bruguière; *MUREX*, Linnæus). This genus of shells has very properly been separated from the confused Linnæan genus *Murex*, in which was included all the species not having thickened bands, without distinguishing the genera *Pyrula*, *Pleurotoma*, and others, now forming well defined genera. The shells of this genus, as it is now established, are of a fusiform or spindle shape, whence the name; the whorls ventricose at the lower extremity, and without varices, or longitudinal thickened bands on the spire or body. The columella is rarely plaited, as in the *Fasciolaria* and *Turbinella*, the right lip exhibits no slit, as in the *Pleurotoma*, and the long produced turreted spire clearly distinguishes them from the *Pyrula*. These molluscs may be described generally as being turreted, with a transverse or nodulous keel, sometimes striated longitudinally; the columella plain; aperture canaliculated at the base, and ending in a channelled beak, frequently longer than the spiral whorls; the right side of the

aperture in adult examples is always toothed or crenulated; it possesses an epidermis, and an oval shaped horny operculum, with a lateral summit. Lamarck enumerates thirty-seven recent species all marine shells, three or four of which inhabit the northern regions, the others are only found in the eastern seas. France furnishes numerous fossil species, and they are also often found in this country. For their classification, see *MUREX*.

**GAD-FLY.** A term of indefinite signification applied to various species of dipterous insects which are troublesome to horses and cattle. In the Introduction to Entomology, Messrs. Kirby and Spence apply it to the species of *Æstridæ*, giving to the *Tabanidæ* the name of horse-flies; but in "The New World of English Words throughout the Artes and Sciences," published in 1658, we find the "gaddefly" described as a certain insect which stings cattle, called also a "brie," and the "brie or brieze" is therein described as a kind of fly, called a horse-fly or gad-fly. Now as the *Tabanidæ* alone sting or rather bite cattle, and as the term breeze has certainly occasionally been applied to the insects of the other family, it will prevent all further confusion by describing the two groups of insects, and their respective modes of tormenting these useful animals, under their scientific family names.

**GADOIDÆ**—the Cod family. A family of soft-finned fishes with sub-brachial fins, or with the two under lateral fins, which answer to the hind legs of the mammalia, situated on the throat immediately under the gill-openings. They compose the first of the three families into which Cuvier divides the soft-finned fishes which have their under fins below or in advance of the pectorals, and the bones which support those fins are joined immediately to the bones of the shoulder. The family consists only of two genera,—the great genus *Gadus* or cod, and the genus *Macrourus*, to which the continental ichthyologists give the name of grenadiers. The last genus consists of only two species, and these are but little known. They inhabit the depths of the Mediterranean, and of some parts of the temperate regions of the Atlantic. They are not very often caught, and their manners are obscure; but we shall have to give some short notice of them in a subsequent part of this article.

The genus *Gadus* on the other hand is exceedingly numerous both in species and in individuals; and taking them altogether they may be regarded as the most valuable fishes in the sea in an economical point of view. They are caught in vast numbers, many of them are of large size; and though there are differences of flavour in the different species, and even in the same species, according to the ground on which it happens to feed, and the condition in which it is when taken, the flesh of the whole is light, wholesome, and agreeable. It possesses another advantage over that of most fish, that it admits of being more perfectly cured by salting, and in this way, either salted moist, or dried, it furnishes a vast quantity of food for the inhabitants of those countries where, from the nature of the seas, or from the countries being situated inland, fish in the recent state cannot be obtained. If we take this genus altogether, perhaps they are more wholesome and also better flavoured than almost any other fishes; and, though this circumstance lessens their value in the estimation of those who are curious in fish, yet they are, gene-

rally speaking, cheaper than any other product of the sea, or even of the land, which remains equally long in season. The flesh of the whole of them is remarkable for its whiteness; and they are on this account called white-fish, and the establishments for the capture of them the white fishery.

They are rare, if found at all, in the tropical seas; but they are very abundant in the cold and temperate ones, the north Atlantic, up almost if not altogether to the polar ice, being the grand place of their resort. When they are most in season they are, generally speaking, gregarious, resorting to the banks in countless multitudes; but it is generally understood that when they quit those banks they do not remove to any very great distance, so that by judicious management on the part of the fishers, it is probable that some of the species might be found in abundant numbers and in good condition all the year round.

In a genus so numerous there must of course be different degrees of productive power in different species, but taken on the whole they are among the most prolific of fishes. The common cod fish, which is, taking both quantity and quality into account, the most valuable of the whole, multiplies at the rate of between two and three millions at a single spawning; so that it is altogether impossible for any fishing which men can carry on very much to thin their numbers.

The general characters of the cod family are: the body moderately elongated but tapering considerably to the tail, and a little compressed laterally; the skin covered with soft scales, of medium size or rather smaller, but the skin of the head without any scales; the jaws and the posterior part of the vomer covered with teeth, which are of unequal size, but generally rather small, and placed in several rows arranged card fashion, or the tooth in the one row against the interval in the other; the gills and gill-openings are very large; the gills consisting of seven rays; all the fins are soft, with the exception of a single ray in the anal fin in some of the species; in general there are two or three dorsal fins, of which one or two are in rear of the vent; the caudal fin is very distinct; and the ventral fins are attached to the throat, and pointed at the extremities. In some of the species the gape is very wide; in all the stomach is in the form of a large pouch, very strong, and there are numerous cœcal appendages, and a long intestinal canal. They are all provided with a large air bag, which is sometimes notched or toothed at the sides. The species are so numerous, however, and differ in so many of the details of their character, that it is impossible so to frame a general description as that it will meet them all.

Though these fishes are seasonably gregarious upon the banks, in the same manner as the flat fishes, they inhabit places of somewhat different character even then, and at other times they are much more discursive through the waters. It does not appear that they feed much upon ground substances, but rather upon the fry of other fishes; but in this respect the habit varies considerably along with the species. In some, as in the common cod, the young are rarely seen near the shores, but appear rather to reside near the banks. Others, again, in their young state, literally swarm on the shores, and in the harbours, and appear to prefer running water, whether of tide or of current to that which is more still.

While some of the species are found only on banks,

or where there are rich bottoms, others of them frequent rocky grounds, and those which do so are, generally speaking, smaller in size and firmer in their flesh than the inhabitants of the banks. Taking the British seas altogether, there are perhaps more species on the south coasts; but the numbers increase northwards. The sea on the east coast, which is full of banks, the mouths of the rivers, and also in mid-seas where the currents of tide meet and form their deposits, these fishes are very abundant. In this sea they are, however, usually found at a good many miles distance from the land, unless it be in the species which resort to the shores, and which are always inferior in quality to the far sea ones. In the western seas they are perhaps even more numerous; and along the west coast of Ireland, and especially on the west of Scotland among the isles, where the disturbed currents of tide have deposited numerous small banks, they are found in numbers which are almost incredible, not on the banks only but in the channels, and openings of the sea lochs, or deep and narrow bays by which the coasts there are so much indented. They are also exceedingly numerous among the northern islands; and perhaps there are as abundant fishings near the Shetland islands as in any other part of the British seas. Indeed, white fish of some species or other, either fresh from the sea, or dried in the sun, or salted, forms a very large item in the every day food of the people there. The same may be said of Iceland, of the Faroe islands, and of many parts of the coast of Norway. The grand head quarters of the race, at least of the common cod, in an especial manner, seems to be the great banks of Newfoundland, which are, perhaps, taken altogether, the largest deposits of sand, gravel, and mud, which is any where to be met with. From this, they spread themselves in the direction of the current of the water, which may be said to set from this bank across the Atlantic, and to extend as far to the south as the shores of the bay of Biscay. The species which are most abundant differ a good deal at different places of this wide range of the sea; but still, taken on the whole, they are more numerous here than in any other part of the world; and they give a value to those seas which no other seas can be said to possess.

When we say that the range of these fishes extends as far southward as the bay of Biscay, we must not be understood as implying that they are distributed in equal numbers through the whole of this range; for the numbers diminish as we proceed southwards, while the great mass may be regarded as not extending much further to the south than the coasts of Scotland. The species most abundant and best, to the south of this, is understood to be the common cod; and there is no fishing on the south coast of England for any of them which can be regarded as very productive, unless it be for the whiting, which is far from being one of the most valuable. Some rare ones are occasionally met with on the southern shores that have not been noticed in the north; but then, on the other hand, there are several so numerous in the north as to be taken both for local consumption and for sending dried or salted to other markets, which are very rare in the south. We shall be better able, however, to notice the few particulars with regard to locality which our limits will afford, when we come to speak of the different species. The genus has sometimes been divided into as many as seven sub-

genera ; but we shall not formally notice their distinctions.

**COMMON COD** (*G. morhua*). This is the species which is most valuable as an article of commerce. The fins are large, the body is thick toward the head, and tapering to the tail ; the first ray of the anal fin is spinous ; the colour above is grey freckled with yellow ; and that below is white. The lateral line is straight till opposite the vent, but bends toward the tail, where it becomes white and broad. The termination of the caudal fin is nearly straight. It is understood that, in the British seas this fish deposits its spawn in the spring ; but from the fishing season, as afterwards to be mentioned, on the great bank of Newfoundland it is probable that the spawning time there is different.

The following account of the fishery on the great bank of Newfoundland will show the immense value of the common cod in a commercial point of view :— On the east and on the south of the island there are several banks of sand, that rise from the bottom of the river, the greatest of which extends nearly ten degrees from south to north. The stillness and comparatively mild temperature of the water, in their vicinity, attracts so many shoals of cod that the fisheries which are established there supply that article to the greater part of Europe. These animals quit the banks about the end of July and during the month of August. The fishing season begins in April, and ends in October. The length of the cod seldom exceeds three feet, and the conformation of its organs is such as to render it nearly indifferent to the choice of its food. The voracity of its appetite prompts it to swallow indiscriminately every substance which it is capable of gorging ; glass and even iron have been found in its stomach ; by inverting itself, it has the power of discharging these indigestible contents. The fishermen range themselves along the side of the vessel, each person being provided with lines and hooks. As soon as a fish is caught, they take out its tongue, and deliver it over to a person in whose hands, after having undergone a certain degree of preparation, he drops it through a hatchway between decks, where part of the back bone is cut off, and the cod, in order to be salted, is thrown through a second hatchway into the hold. Whenever a quantity of fish, sufficient to fill one of the vessels, has been taken and salted, she sails from the banks to the island and unloads her cargo. The ship returns again to her station, and in the course of the season completes four or five different freights. The fish are dried on the island, and larger vessels arrive from England to convey them to the European markets. Much care and attention are required in packing this article ; the greatest precaution is used to preserve it from the moisture of the atmosphere. A person denominated a culler, or inspector, attends the loading of each vessel, in order to see that all the fish are completely cured before they are put into the cargo, which might otherwise be soon damaged. The price of dried cod at Newfoundland is commonly fifteen shillings the quintal, and is sold in Europe for about a pound sterling. In a vessel with twelve men there must be 10,000 fish caught, salted, and brought into market from the middle of April to July, else the owners will be excluded from all claim to the established bounty. Such a crew, however, takes usually during the season more than double that quantity. The English merchants, who are engaged in these

fisheries, supply the sailors upon credit with whatever they stand in need of, and are repaid at the end of the year with the produce of their industry. Several hundred thousand pounds are thus annually advanced on an object of commerce before it is taken from the bosom of the deep. About 400 ships, amounting to 36,000 tons' burthen, and 2000 fishing shallops of 20,000 tons, are usually employed during the fishing season. Twenty thousand men from Great Britain and Ireland are engaged in this trade, and several thousands of them, who remain on the island during the winter, are occupied in repairing or building boats and small vessels, or in erecting the scaffolds for drying the cod. The persons that are not seafaring men have been distinguished by the appellation of planters. Some idea of the value of the Newfoundland cod fishery may be formed, by its being mentioned that the British alone have taken in one year as much as nearly 100,000,000 pounds weight, yielding a gross revenue of at least 2,000,000*l.* sterling.

The fisheries on our own shores do not, and cannot, afford anything like such a revenue as this from foreign trade ; but, from the way in which the northern parts of the island especially are divided by bays, and from the fish surrounding the shores there in almost every direction, the fishing, if properly carried on, would be far more valuable, in a local point of view, than if there were some one fishing ground of much greater extent than even the whole put together. It is to be regretted, however, that this fishery, widely spread as it is, easily as it might be carried on, and inexhaustible as one of the supplies of human life from the vast productive powers of the fish, has never been prosecuted with that skill and industry which its importance demands. We have already said, that there is none of the genus so abundant on the south coast of England as to afford more than a very moderate local supply ; and, though the banks between the shores of England and the Netherlands are frequented by numbers of cod, which grow to a large size, and are understood to be finer in flavour than the east coast ones more northerly, and toward and beyond the middle latitudes of the island, yet it does not appear that anything farther than a local supply can be obtained even there. Toward the land, both on the British and the Netherlands side, the cod-fishing ground is intercepted by water apparently rather shallow for cod, and which is accordingly more occupied by flat fish, by soles perhaps, more than any other species toward the British coast, and by turbot probably toward that of the Netherlands. With the exception of the supply for the London markets, and that is, in a great measure, in the hands of monopolists, the white fishing appears to be sadly neglected on the east coasts of England ; so that it is doubtful whether a single barrel of white fish is salted for foreign sale annually between Dover and Berwick, while the quantity carried into the interior is astonishingly small, considering the extent and rapidity of land-carriage which is now established in every part of the country. This is probably more sincerely to be regretted than it is to be remedied ; but, from the price at which excellent cod is often sold at the coast towns farther to the north, it is extremely probable that proper attention to the fisheries might procure for any man, at any spot within the four seas, a fair-sized cod fish, in good condition, at an average price of not greatly, if at all, exceeding one shilling. The price on the coast, at the places to which we allude,

may be from fourpence to sixpence, when the fish is most plentiful and in best condition; and surely, if a proper system were established, the same amount might carry it halfway across the island.

On the southern part of the east coast of Scotland, and indeed as far to the northward as the Moray Firth, cod can be regarded as affording no more than a local supply, and that only to a short distance inland, as is the case in the southern part of the island. Cod is not indeed a very favourite fish on that part of the coast. It is said to be of inferior quality to that taken on the banks farther to the south; and, at all events, it is chiefly bought by the poorer classes of the people, who get it cheaper on the spot, in consequence of its being held in comparatively low estimation; but this circumstance greatly lessens the inducement to fish for it, and, consequently, the quantity taken. The haddock, another, and, when taken on the proper ground and in prime condition, a far more delicious species, is the favourite white fish on the last-mentioned line of coast; and so much is it esteemed above every other production of the sea, that even the sole and turbot fisheries, for both of which there are understood to be good grounds in many places, have never been able to create such a demand as to induce the fishers to carry them on expressly, and with a requisite degree of knowledge, experience, and vigour.

This preference may be said to extend nearly the whole way to the north-eastern extremity of Scotland; for, though cod is caught in considerable abundance, the greater part of it is, we believe, dried, with the exception of what may be consumed in the fishing villages and their immediate neighbourhood. And here, as on the more southerly part of the east coast, the haddock is still the favourite fish for local consumption; and when we come to notice the characters of that species, we shall probably be able to show that this preference given to it is not a mere prejudice, but that it is really better there than on almost any other part of the British shores. When we come to the Pentland Firth, and to the various bays and banks among the Orkney and Shetland Islands, we have arrived at the grand rendezvous of the northern members of the cod family; and though the common cod is not the most abundant, or probably the most highly prized in those seas, it is taken in considerable numbers, and exported, cured, or more properly speaking, dried. The fishermen there, being of northern extraction, or descended from the sea-kings of old and their followers, are more adventurous and at home upon the waters than in many other parts of the country. But it is singular enough that they will not bear transportation to other localities; for colonies of them, which have been carried to the western islands at considerable expense, for the express purpose of establishing fisheries, and teaching and stimulating the natives, have, in the course of a few years, sunk into the same state of indolence and disregard of the vast and almost constant harvest which the sea around them affords. They have, after the lapse of a very few years, lolled indolently on the land, contenting themselves with daily meals of potatoes and salt, and leaving the remains of the boat high and dry, to be beaten and consumed by the wind and rain, while two hours' use of that boat would have provisioned their families for a week, and one good season, duly improved, might have rendered them independent for life. Nor is there any more unfortunate demonstra-

tion of the truth, that men will not exert themselves unless they are pinched, and also stand in some jeopardy of degradation, than the fact that, in many places where the sea is most rich in fish, and they are nearest to the land, the fewest are taken out of it.

As a proof of the advantage that might be derived from those western isles' fishings for cod, we may mention, that the late Sir Hector Mackenzie of Gairloch established at Gairloch, on the west coast of Ross-shire, a fishing village, to which there belonged twenty boats, each having about four hundred hooks on the lines, and that this small fishery produced every year twenty thousand cod fit for exportation, besides an ample supply to the villagers and the neighbourhood from the under-sized cod, and the other fish accidentally taken on the cod-lines. The cod there are rather small in size, averaging about five pounds weight each when they are cleaned, have the heads removed, and are ready for salting. They are, however, of very superior quality—proportionally thicker, firmer in the flesh, and more delicate in the flavour, than Newfoundland cod. Whether this fishery is still carried on, we are not informed; but, as the adventure was Sir Hector's own, and he was at that time the only proprietor who had spirit enough for such an enterprise, it is possible that even this may now be abandoned. But, when it was in the condition we have mentioned, it was generally understood that, by an additional number of boats, the produce might have been more than doubled; and thus two hundred thousand pounds weight of excellent fish might, from this little spot alone, have been added to our annual store, while many industrious men and their families might have earned a comfortable living, by winning this treasure from the deep, and adding it to the wealth of the country.

This is one very small and local proof of the great advantage which might be derived from the countless myriads of this species of fish which throng around those remote shores of our island; and we are within the mark when we say, that the ground alluded to is not anything like a tenth, or even a twentieth, of what might be successfully fished, so that, from the Hebrides alone, we might annually derive not less than two millions of pounds of fish; and as at those small fisheries, for which salt could be procured at a small expense from Liverpool, by the return of the vessels, the quantity would be superior to that which is obtained at Newfoundland, and would consequently fetch a higher price in the market.

Once, a good many years ago, we observed, on the beach to the northward of the village in the Island of Iona, a pile of dried cod, which must have consisted of many thousands; but whether the fishing is still carried on there, we have not heard, though we think this rather doubtful, because it was described as being in a languishing and expiring state at that period.

It is true that the winds are both inconstant and turbulent among those western isles, and thus there might be both loss of lines and danger to boats; but the islanders are hardy boatmen enough, and show no little skill in their craft, as they can guide a little shallow dril through the waves, and so they would not, if they had good craft, run any very imminent hazard. Somehow or other, however, they do not set much value upon the produce of the sea; and that more than any chance of loss or fear of danger, seems to be the real reason why the fisheries there are not turned to account.

When on their migrations or feeding excursions in the currents, these cod swim near the surface. One can not only see them in crossing the shoal in a boat but they give a whitish tinge to the water at a distance, and seem a sort of "blink" on the sky. One can also find them out by the number of sea-birds—gannets and gulls chiefly—which are whirling about, and screaming on the shore; and ever and anon plunging down; but it is doubtful if they are nearly so successful in cod-fishing as they are with herrings, the shoals of which are still more numerous, swim near the surface, and are more easily taken out of the water. Altogether the shoals of cod give no small interest to the seas, of which we are speaking; and the only regret is, that they should be turned to so little account, in comparison with what might surely be done.

We had almost forgotten to mention that the oil which is obtained from the liver of the cod, answers a very important purpose in the arts. It is valuable as a lamp oil; but that is not its only or its chief value, for there is no oil equal to it for the dressing of leather, for which purpose it is almost exclusively used by the best manufacturers.

**THE HADDOCK** (*G. æglefinus*). The haddock is a much more handsome fish than the cod; the head and gill openings are not so disproportionately large; and the body is altogether of a finer shape, and the colours brighter. The upper jaw is longer than the under one; the tail is forked; the lateral line is black; and there is a black spot on each side, behind the pectorals, which the legend says are the marks of the thumbs of St. Peter, when he took the tribute money out of its mouth, which shows that the founder of the legend could have known nothing of the geography of the fish. The colour of the upper part of the haddock is dusky, and that of the belly pure white. The frontal line slopes, and the eyes are large and bright. The fins are the same in number, character, and arrangement, as those of the cod; but the extremity of the caudal fin is forked, and the whole air and appearance of the fish are different. The haddock is also a much smaller fish; the cod measuring, when full-grown, or at least understood to be so—for the full growth of a fish is a very indeterminate matter—as much as three feet, while the haddock is seldom found of above half that length. The quantities of matter in them are nearly in the proportions of the cubes of the lengths; but the head of the cod occupies so much of its volume, that there seems to be proportionally more flesh on a well-grown haddock than on a cod of the same length. The spawning time is in spring, as well as that of the cod; but the haddock, perhaps, comes into season earlier than the other. On those shores where this fish is best and most esteemed, it comes into season on the usual grounds in May, and continues till the middle or end of January. There is some reason, however, to doubt whether the same individuals spawn every year; for it has been ascertained by actual trial that, by going a few miles farther to seaward than the annual fishing grounds, haddocks in good condition may be found in April, or, perhaps, even in March. We want more information as to the retreats of our white fish, and whether we could or could not obtain a supply in good condition, all the year round, by a judicious shifting of the ground.—There is another thing to be attended to, and that is the length of time over which the spawning extends, which is probably a much longer one than we gene-

rally suppose; and thus those which have spawned in the early part of the season, may have retired and got into good condition again before the others have got through that grand labour of the year.

Haddocks are certainly found in finest condition in the clear and deep water off the rocky shores; and it is worthy of remark, that they appear to be best in the places of any eastern sea which are intermediate between those in which the cod are best. We have already mentioned that the cod, on the southern banks between the shores of England and the Netherlands, and those, again, about the north-east of Scotland, on the coast of Caithness, are better than on the shores of the middle of the island. Haddocks are good upon all the coast from the rocky parts of Yorkshire to the Ord of Caithness, and a little beyond; but they are very superior upon a certain intermediate portion, namely, on that which extends from the Red Head, a little to the north of Arbroath, to the mouth of the Dee at Aberdeen, where the bold rocky shore and the deep and clear water terminate. On the most bold and rocky portions of this shore they are better than on the others, and they are also got nearer to the land than when the shores are of a tamer character. The east coast of the county of Fife is not high, but it is rocky, and they are pretty good there; and so are they off the wild and caverned shores near the Red Head. The coast of Kincardineshire, which is all bold, with the exception of clear, sandy, or pebbly beaches in the bottoms of a few small bays, is perhaps the place where they are found in the very highest perfection.

This is the part of the coast where the partially roasted and partially smoke-dried ones, known by the name of "Finnin Haddocks," are prepared in the best style, partly because the fish themselves appear to be finer than they are anywhere else, partly because they can be prepared in a more recent state, and partly because the people have a superior method of preparing them. To have them in the highest perfection, however, they must be eaten on the spot, and before they are cooled after the original preparation, for those very superior ones cannot be removed to any distance without losing much of their flavour, and those which can bear carriage have to be salted and much more dried, both of which operations spoil their flavour.

If they are to be of the finest zest possible—and when they are, it is difficult to imagine anything more delicious—they must be brought from the sea the same morning they are to be eaten. Small ones should be selected, if sufficiently plump and well-grown, and the flesh should be touched as little as possible. Indeed, a haddock, under all circumstances, is a delicate fish, and cannot bear to be tumbled about, or handled, or sluiced with water, without sustaining very serious injury, which, by the way, may be one of the reasons why it is difficult, if not impossible, to get anything like a good haddock in London.

Holding them by the head, they should be cut open, and wiped clean by gentle pressure, but not washed; and when they are split so as to be flat, they should be suspended on wooden spits from the top of a cask, of which both the ends are taken out, and the cask so built in at the side of the kitchen range, or in any other convenient place, so that there may be room for a fire below. The best wood for the fire is the twigs of juniper; and the smoke and

heat should be received into the cask, a cloth being placed on the top to confine both; but the flame ought not to rise so as to scorch them. In this way they should be done slowly, and the action of the smoke so hardens the surface, that not a drop of the juice escapes. When properly done, the knowledge of which is a matter of experience, and cannot be explained in words, they are to be removed from the cask, the heads separated without touching the bodies, and these rolled up closely in clean cloths, only one in a cloth, great care to be taken not to press or break them, and they ought to be eaten while hot. The spurious ones, which are sent to a distance, are more or less salted, and exposed to the air, and they are merely smoked, without being cooked, as is the case with those that are genuine. These last can of course be obtained only at very particular parts of the coast; and of those places where the fish themselves can be had, there are only a few where the art of dressing them in the best style is known.

Like the cod, the haddock is a gregarious fish, and if the fishermen find any upon a particular fishing ground, they in general make sure of finding numbers. They are, however, much more discursive and capricious than cod, and by no means so true to their grounds for a succession of seasons; though they are understood to be much more true to the haunts in the clear and deep water near the shores, than they are upon the margins of the out-at-sea banks, where their pastures border on those of the cod. The reason of the two not being found in abundance in the same localities is understood to be that the cod prey upon the haddocks, which is not at all unlikely, as cod are exceedingly voracious, have a very capacious swallow, and are miscellaneous in their eating even to the degree of preying upon each other. We need not be surprised at this, however; for the males of many of the mammalia are prone to devour the young, nor are there wanting among them instances in which the female makes a meal of her own offspring. The haddock is not quite so voracious as the cod; but still it has not much to boast of on the score of abstinence.

THE TORSK (*G. callarias*) is a medium sized species, a native of the northern seas, and found most abundantly in the Baltic, especially near the mouths of the great rivers. It is spotted all over, and is very much esteemed for the table. It has been mentioned as a British fish; but the fact of its being so is a little doubtful, at least no specimen has, so far as we know, been seen of late years, or indeed since the species of fishes were so well made out, and discriminated as they are now. The fact of its being found at the mouths of the rivers in the Baltic, where the water contains very little salt, is rather against its being met with in the open ocean, or in any part of the British seas, except as an accidental stray.

THE BIE (*G. luscus*) is a small species, not more than a foot in length, which is occasionally met with in the British seas, but is by no means common, nor does it appear to be abundant or of frequent occurrence in any locality. When it does occur as a British species, it is, however, found indiscriminately on the most northerly and the most southerly shores. Its colour is olive on the back and silvery on the under part. The first ray of each ventral fin is produced in a sort of bristle-shaped elongation. The body is broad but flattened on the sides; the ex-

trernity of the caudal fin is nearly square across; there is a membrane which partially covers the eyes; the jaws have only a single row of teeth curved inwards into the mouth; and the scales are larger than on most of the genus. Its flesh is reckoned wholesome and good; but so little is known of its manners that we are unable to say whether it is or is not gregarious.

THE POUT (*G. barbatus*) is about the same size as the last mentioned species, and like that it is rare on the British coasts; but in appearance and colour it is different. Its back is much arched and the whole body high in proportion to the thickness. Its general colour is dull white, with the fins black, and a dark spot behind the pectoral fins. The first dorsal fin is of a three-cornered shape, with the first ray produced in a sort of fibrous appendage; and the caudal fin is squared over at the end. The scales on the body are very small; the back is furnished with a sort of keel or ridge; the lateral line is broad, curved, and of a white colour. The mouth is much smaller in proportion to the size of the fish than in most others of the genus; and the lower jaw is marked with a row of punctures, seven or eight in number. The English fishermen call it the "whiting pout." It is but little esteemed as food, and probably upon this account it is not seen in proportion to the numbers in which it actually exists. It occurs in the Mediterranean, and also in the more northerly seas; and is understood to inhabit at considerable depths, and to hide itself in the thick beds of sea-weeds.

THE POOR (*G. minutus*) is a small species, about half a foot in length, and very slender in the body; light brown on the upper part, and whitish on the under. The lateral line is very narrow and straight. It is found in the Gulf of Venice, the Mediterranean, and the Atlantic, where it resides in the deep waters during the winter months, but comes to the shores in the spring. In itself it is of little or no value; but its appearance is, on some of the coasts, hailed with joy by the fishermen, who, upon its coming, prepare for the capture of the larger and more valuable species of the genus, which appear soon after it, and appear to follow it and feed upon it, which brings them near to the land.

The species which we have now enumerated are the principal and most valuable of those which constitute the sub-genus *Cod*, properly so called, with those systematists who sub-divide the family into sections; and the sub-genus is styled *Morhua*, from the trivial name of the common cod. We shall now proceed to the other sections, still retaining the common generic name *Gadus*, as the family are all nearly allied to each other.

But before we do this there are a few observations in supplement to this division which may not be uninteresting to the reader, some of which refer to the common cod, and others to this division or to the family generally; and the great value of these fishes renders every thing that can tend to illustrate their character of considerable public interest.

Of the common cod, there appear to be three varieties in the British seas; but whether the differences have or have not been wholly produced by locality and nature of ground, we have not the means of ascertaining. The southern cod, that which is found on the banks off the English coast from the Spurn to Kent, and which also occurs in the English Channel, though not so abundantly, appears to

be resident in those seas, and is very rare in the north. It is more of a yellowish colour than that of the northern cod, its head is smaller and longer, and it perhaps also attains a larger size. On the banks we believe it is always taken by the hook and line; but in the Channel it is hauled for.

On the rocky grounds in the middle latitudes on the east side of the island, and probably also on the west, in the channel between Britain and Ireland, there is another variety, known as "rock cod," which it of a much redder colour, smaller in size, and much firmer in flesh. This one frequents much the beds of sea weed, and is understood to feed a good deal upon crustacea, especially crabs at the time when they cast their shells. The head of this is not quite so much elongated as that of what we have from its locality called the southern cod, but it is rather more so than the head of the northern. It does not appear that this variety is very discursive from its locality; for though it can be had abundantly on the rocky bottoms on the northern part of the English coast, and the southern part of the Scottish, it is found only as a straggler in the south; and we believe that the same is the case in the north. In as far as popular observation is concerned, these two varieties are easily distinguished from each other; but they agree in all the characters upon which naturalists found the species.

The third is the northern cod, and which is sometimes called "Scotch cod," it being most plentiful on the coast of Scotland, though, as we have mentioned, the rock or red cod is also found there, and this one occurs on the more northerly parts of the English coast. This one has the head much larger in proportion, that is to say, much thicker and rounder; the gape and the gill-openings are also wider, and the body tapers nearly the whole way from the gill-openings to the caudal fin. This is the one which is found both on the east and west coasts of Scotland. It appears to be more discursive than the others; and it is probably the same which is met with on the bank of Newfoundland, and generally in the Atlantic outside the British islands. Its quality is understood to depend a good deal on the place where it is taken, being best where the water is deepest and has most current, though the size is perhaps inferior there. Even in this, however, there is no specific difference from the others; and from what we know of the effects of different waters in changing the qualities of trout, and other fresh water fishes, we may naturally suppose that not cod only but all others will be affected by similar causes in the sea.

The other point to which we would call attention, and it is by far the more important of the two in a general point of view, is the geographical distribution; not only the cod, properly so called, but all the more valuable species of the whole genus, are confined to the temperate and cold latitudes of the Atlantic. The same may be said of the herring family, and indeed of all those fishes which have value in a commercial point of view, or in any other point of view than that of merely supplying the people who live near the shores.

The only species, we believe, which is met with in any part of the Pacific is the coal-fish, to be afterwards described, and though it is exceedingly numerous upon many parts of our coasts in the young state, and especially so in the north when full-grown, it is far from being the best of the genus; so far indeed

that, in point of flavour and also of nutriment, it may probably be accounted the very worst of the whole.

The fishes of this family, besides being inferior in their qualities, are also far more prolific than any others; and as they are, either seasonally or in the different species, both *littoral* and *pelagic*, they occupy a greater breadth of sea as their pasture than any others. The common cod has been already mentioned as an instance of very great productiveness, but it is by no means the most productive of the family. The ling, a more northerly fish, and one which is in some respects superior, very superior when salted and dried, has still more eggs in the roe than the cod, the number being between nine and ten millions, a rate of increase on which all the fishing that can be practised cannot have the slightest perceptible effect; for, if it had scope for full working, it has power enough for turning the whole matter of the earth into ling in the course of a very short period of years. This is of course, practically speaking, impossible, but still the power exists, and the existence of such a power is constantly seen working for the benefit of man, in so far as he has industry and skill for taking advantage of it.

One cannot fail in being struck with the peculiar fact that all this vast productiveness of food in the sea should be concentrated into the northern part of the Atlantic; for the vast shoals of the cod family, and we may add those of the herrings, are confined to between the fortieth and sixtieth degrees of north latitude, or are found only accidentally and straggling beyond those limits.

This, however, is not the only or even the especial peculiarity of this portion of the sea; for, though it is foreign to our present purpose, we may just remark in passing that the Atlantic is, above all others, the ocean whose showers and gales produce fertility on the adjoining lands. It is especially the ocean of tides and currents; its shores abound more than any others in creeks and bays; and the quantity of supply which it receives from rivers is greater than that of any equal extent of sea, scarcely less indeed than that of all the other seas on the surface of the globe. It is thus the best for navigation, and the promotion of that intelligence and industry which are the results of a free, easy, and speedy communication between the inhabitants of different lands. This is a very delightful subject; but it would be contrary to the plan of the present work to enter farther upon it in detail, though we heartily recommend it to the attention on our readers, and so revert to our more immediate subject.

If we were to follow the sub-divisions of the genus *Gadus*, the next is *Merlangus*, the whiting section, agreeing with the cod in the number and arrangement of their fins, and differing, in the common characters of classification, only in having no beard or fleshy appendage to the lower jaw, whereas the true cod have one, and some of the others, to be mentioned afterwards, have more. The typical species is,

THE WHITING (*G. merlangus*). This is a very common species on most parts of the British shores; and by fishing nearer the shores at one season, and farther out at another, it may, generally speaking, be caught in tolerable condition the whole year round. It is a smaller fish than the more valuable of the true cod, and its flesh is, generally speaking, soft and rather insipid; but when in very prime condition, which it is in the spring and summer months, it is

esteemed as light and delicate. Like all other fishes, the whiting varies much in length, but the average is about a foot. The upper jaw is the longest, and the teeth in that jaw are long. The colour on the upper part is pale brown; the sides and belly are silvery, more or less marked with pale yellow; and the lateral line is straight and white. The whole fish has a rather delicate and semi-transparent appearance.

The whiting does not perhaps range so far to seaward at any season as some others of the genus. In the summer months, at least, it remains much closer in than the others, feeding on the fry of herrings and other fishes which deposit their spawn near the shore; it also feeds on crustacea and mollusca. Indeed, though the whiting is a delicate fish to appearance, it partakes of the voracity and miscellaneous feeding which are characters of the whole tribe. Different from what is the case with most of the others, the whiting is understood to be fattest and in best condition upon the flat shores and rich bottoms, though its flesh is said to be firmer when it inhabits the rocky grounds. Whiting, though far from being so substantial as an article of food as many of the others, is understood to be more light and easy of digestion, more so indeed than perhaps any other fish; and thus it is an aliment well adapted for invalids. Whiting is generally eaten fresh; but it is also salted, though it does not answer quite so well for that purpose as those species which have firmer flesh.

**THE COAL-FISH (*G. carbonarius*).** This is a very common species, found upon most parts of the British shores, though much more rarely on the southern than the northern. It is a very active fish, and found most abundantly in rocky places, or in currents and tideways. When young it occurs in vast shoals at the entrances of harbours, and in all places where there are runs of water near the land; in which places vast numbers are caught, with rod and line, by the boys and idlers, but they are of no great value. In this state it is small, not in general larger than a sprat, and by no means so well flavoured as sprats are when they are newly taken, but it can be longer kept. In this state it is the "podlie" of the Scotch coasts, the fishing for which, at the ends of the piers and jetties of harbours, is reckoned the most inglorious of all fishing. In this young state the upper part is dusky, and the under part dull white; but the colours of the full-grown fish are different.

When full-grown it reaches the length of two or even three feet. The upper part, including the caudal fin, is then black, but dull and with a tinge of leaden blue toward the sides. The under part, including the ventral and anal fins, is white; the head is small, and the form of the body rather elongated. The tail is very broad and forked, and the fish keeps the water which is put in motion by the tide or otherwise, and swims with much vigour and rapidity. In this state, as well as when young, these fishes take the bait very greedily, and thus are more easily caught than almost any others; but they are tough and leathery, so that they are nowhere very marketable. They are, however, used both in the recent state and salted; and from their cheapness, they are eaten in great numbers by the labouring people on the poorer islands and parts of the coast. The Shetland isles are their head-quarters, in so far as the British dominions are concerned; and so numerous are they on the coasts of Scotland and its islands, that they have about a dozen local names in different parts. In the

Shetland isles they are called piltocks, and as the cows are said to eat herrings on some parts of these islands, so the poor people very generally, and at all meals, eat piltocks. It is reported that a traveller in those isles, meeting a boy in the forenoon, and not getting a very ready or clear answer to some other questions, asked him what he had had for breakfast that morning. "Piltocks," was the immediate answer. "What do you expect for dinner?" asked the traveller. "Piltocks." "And what for supper?" "What could any body get at our time but piltocks?" This is the species which is mentioned as being numerous on the northern shores of the Pacific; but we believe that specimens brought from there have not been very carefully examined in Europe.

**THE POLLACK (*G. pollachius*)** does not grow to the same size as the coal-fish; and is not found in places of exactly the same character; but still it is very common on the rocky parts of the coasts. As is the case in the coal-fish, the lower jaw is longest. The eyes are large, the irides of a brown colour, the upper part is dusky green, the sides marked with yellowish streaks, and the belly white; the line of the back slopes from the first dorsal fin; and the tail is squared over. The average length when full grown is understood to be about a foot and a half. These are very active fishes, and sport about in the utmost violence of the sea. They are often found in vast shoals, and are easily taken; but their flesh is not held in much estimation, excepting where the better species are not to be had.

**THE GREEN POLLACK (*G. vireus*).** This species is by no means uncommon in the larger tidal estuaries of the northern parts of Britain, and it is frequently caught but not much valued. It is more abundant, and more attended to on the coasts of Norway. The upper part and upper fins are green, and the under part white, the fins being marked with numerous black spots. The teeth in the upper jaw are numerous, and very strong in proportion to the size of the fish which, on the British shores at least, is rarely if ever so much as a foot.

These are the principal species of that section or sub-genus, of which the whiting is considered the type; and, taking them altogether, they are of far less value in an economical point of view than the former, or than many of those that remain still to be noticed. They are, perhaps, more active than any of the others, and they come in greater numbers near the shores, and into the tideways, and are much more easily caught. The next division is that of which the common hake is the only known species; and, from the trivial name of that, the division is called *Merluccius*; the distinguishing character is having only one anal fin.

**THE HAKE (*G. merluccius*).** This is a much more southerly species than most of the genus; and is mentioned by Cammeron as abounding in the southern hemisphere. It is also met with in the Mediterranean more plentifully, perhaps, than any of the others. On the coasts of Scotland, especially the east coast, it is very rare; it is less so among the more southern of the western isles, and also on the south coast of England. But the west coast of Ireland is the part of the British dominions where it is most plentiful, especially the coasts of Mayo and Galway. It is an active fish, ranging and discursive, and thus appearing only seasonally on the coasts; but it is gregarious, and when it does appear on its regular grounds, and

not merely as a stray, it appears in great numbers.—It is at all times rather a harsh fish, and when not in good condition it is peculiarly tough and dry. It is best when salted and dried; but even then it is hard, and requires to be beaten to a sort of fibrous powder before it is dressed. It is a large fish, very often caught of the length of three feet or more.

The next division is that of which the ling is the type; and, from the trivial name of that fish, the division is styled *Molva*, or sometimes *Lota*, after the burbot. The leading three characters are—the head flattened; the body elongated; the second dorsal and anal fin long, and their rays of nearly equal length.

THE LING (*G. molva*), has the body long in proportion to the diameter, but very plump and compact in flesh. The upper jaw is longer than the under; the caudal fin is rounded at the extremity, and marked with a dusky bar. In the characters of all this division, there is, indeed, a slight approximation to those of the eels. The upper part of the ling is olive grey, and the under part white, which is also the colour of a narrow margin on the dorsal and anal fins.

The ling spawns in spring, at the same time with the cod, so that the two are in season together. Indeed, they inhabit nearly the same parts of the sea, only the ling is rather the more northerly fish of the two. On the north coasts of Scotland, and among the northern isles, it is equally numerous with the cod, if not more so; but southwards it is rather more rare; and rarer still toward the south of England. It does not appear that there is any southern variety, or, indeed, any variety at all of the ling, as there is of the cod; and, therefore, we know it chiefly as a northern fish. It is, as has been already remarked, among the most prolific of all fishes, and it has been observed of fishes of the same family, that those which have the body most elongated, are in general the most prolific. In those seas where it is found, the ling is taken for a supply of fresh provision as well as for salting; but as it is the most marketable of all the salted and dried fish of large size, which are prepared in the north of Scotland and the northern isles, it is chiefly salted and dried there, the process being frequently no more than spreading the split fish upon the rocks, and watering them from the sea. It attains a larger size than the cod, though it is not so thick at the anterior part. From three to four feet is the usual length of ordinary sized ling, but specimens five feet in length are not uncommon. The summer is the fishing time; and when the liver of the fish is white, the fish itself may be considered as in condition; but if the liver is coloured, it is not wholesome. The liver of the ling gives an oil similar to that of the cod, and applicable to the same purposes; indeed, it is probably finer and more transparent. Altogether the ling is one of the most interesting and valuable fishes in those seas which it inhabits, and it is quite a treasure to the northern people.

BURBOT (*G. lota*). The jaws in this species are of equal length, and the caudal fin is oval, and even a little pointed at the termination, something approaching in shape to that of an eel. The length varies from one foot to three, and upwards; the ground colour is brownish, with blotches of pale yellow and olive. The first dorsal fin is short, and consists of eleven rays; the second fin extends along the back, almost to the caudal fin, which is another approximation to the eel family. It is a river fish, and not a sea one; and as a British fish it has been found in the slow

streams of the rich parts of England only. Different from those which inhabit the sea, it spawns about the middle of winter; and it differs from the eels in spawning in the cold season, and not descending the rivers, so far as has been ascertained, for the purpose of maturing its spawn. The common English name "burbot" is a contraction of "bird-bolt" a kind of short arrow shot from a cross-bow, which this fish is understood to resemble in shape, and after which it has accordingly been called. It is also named the "eel-pout," and the "coney-fish." It is understood to lie in watch for its prey, agitating the barbels on its mouth, as if they were moving to attract the small fishes upon which it preys; and when they come within its reach they are seized and swallowed. Its gape is large, and it is furnished with seven rows of teeth, so that there is little chance of escape for any thing that once gets within its jaws. Its body has the same slippery covering as that of the eels, so that though taken in the hand, the hold of it is not easily retained. Its flesh is very white, and much prized for its flavour; but the roe, the individual eggs of which are very large, are understood to be unwholesome, and difficult of digestion. It is furnished with a very large air-bag. On the continent it is found much more abundantly than in Britain, and it also occurs farther to the north, being known in Sweden and Norway, while in the more sluggish-currented of the German rivers it is very abundant. It is a singular fish: the general organisation is decidedly that of the cod family; but the form, some parts of the organisation, and also both the habits and the locality, approach to those both of the eels and the blennies. It may be considered as among the most anomalous of all the British fishes.

The next division are the Gades, of which the trivial name of the common gade, *Mustela*, has been taken for the sub-generic name by many, and the name *Gadus* by others. In the south of Scotland the common pike is called the "ged," but it must not be confounded with the gades of the cod family. The characters are—the first dorsal fin very small, and the head of moderate size. There are several species which come under this division.

FIVE BANDED GADE (*G. mustela*). This species has, as the trivial name imports, five filaments or bands on the anterior part of the head. Of these four are on the upper jaw, and one on the under. Two of the upper ones are on the fore part of the mouth, and the other two immediately over them. The remaining one is on the middle of the lower jaw, similar to that in the common cod. It is a sea fish, found on the coasts both of England and of Scotland, but more frequently on the former, where it is called the "scallock," the "whistle fish," and the "rockling," the last of which names points out the kind of ground on which it is most common. It also occurs on the coasts of Germany, and in the Mediterranean. It is about a foot and a half in length, generally olive above, and whitish on the under side; but its colours are subject to considerable variations, and it is often found spotted, and sometimes nearly white all over. It is chiefly found among the seaweed about rocks, where it feeds on crustacea and mollusca.

THREE BANDED GADE (*G. tricirratus*). This species is about the same size with the former, but, as the name implies, it has only three appendages, one of which is on the lower jaw, and two on the upper. Its colour is also different; and all the rays of the

dorsal fin are short, while in the five-banded species, the first one is long. The young fish is reddish brown, but after it grows the length of seven or eight inches it becomes reddish yellow, with large dusky spots. It is, perhaps, more common on the British shores than the former; but its haunts and manners are similar, and some regard it only as a variety.

**SILVERY GADE** (*G. argentarius*). This species has been but little noticed, and in Britain only on the south coast. Its manners are accordingly very little known. The specimens which have been met with have been very small, not exceeding two inches in length; and the colours were bluish green on the upper part, and silvery on the under. It may possibly be the fry of the five banded gade; and indeed there is some obscurity about the species or varieties which come under this division. They are, however, of little importance for popular purposes, as none of this division of the genus are of much value, and it would be inconsistent with our plan to go into the niceties of museum specimens.

The next division of the genus is that of which the tusk is the type; and, from its trivial name, the division is called *Brasmus*. Some of the species are a little confined and obscure, but others are well made out, and of much interest and value.

**THE TUSK, OR COMMON TUSK** (*Brasmus*). This species must not be confounded with the *torsk*, which is a spotted variety of the common cod, having the same arrangement of fins, one-barred on the lower jaw, and all the characters of the common cod, except being spotted with brown, which the common cod is not, though often with dull yellow. As a British fish, the tusk is chiefly found in the most northerly seas, where it attains the length of about two feet. It is a bank fish, and caught in the same places as the common cod and the ling, the last of which it most nearly resembles in flesh. As is the case with ling, it is not so much relished in the recent state as cod, but, when salted and dried, it is a very superior fish, and tusk and ling are often associated together. It has the small dorsal and the anal fin lengthened, the ventral fins fleshy, the pectorals and caudal rounded at their terminations, and most of the fins margined with white. The colour on the upper part is dusky, that on the sides yellowish, and that below white. It is one of the most northerly of the whole of the cod family as a British fish; but on the banks among and near the Shetland islands it is far from rare.

Some other species of tusk have been mentioned, as one of a yellowish colour, occurring near Newfoundland, but not common, and another in the Mediterranean, with a single dorsal fin. The first may be merely a coloured variety of the tusk of the north, and the other seems to be somewhat doubtful; at least, it would be rather singular to find in the Mediterranean a fish which is known only in the extreme north even as British. This, however, is not a point for popular discussion.

Another division is named from the fork-head, the trivial name of which, *Physcis*, is used as the general name of the division. The species are somewhat involved in obscurity.

**THE COMMON FORK-HEAD** (*G. physcis*) is a species occasionally met with on the south-west coast of England, but it is rather of rare occurrence. It is usually found about a foot in length; it has large eyes, with white irides; the first dorsal fin is trian-

gular, with the first ray produced; the ventral fins are twice the length of the head, placed far forward on the throat, and each consisting of a single ray, forked, or divided into two braches. The lateral line is curved, and the extremity of the tail rounded. The head is very large. The one now mentioned appears to be a southern fish, and is not met with on any of the northerly coasts of Britain. There are some others, which have been confounded with the hake, and also with the blennies. One, the *Phico* of the Italians, occurs in the Mediterranean, and on the west coast of Spain, and an occasional stray appears on the south coast of England. The head and pectoral fins are red in the spring months.

**THE THREE-FORKED HAKE**, of British authors (*Raniceps trifurcatus*), has the head flat, the mouth wide, the first dorsal fin very obscure, and is said to be about two inches in length. Little is known respecting it, and it does not appear to be a fish of very much interest.

The genus which Cuvier appends to the cod family, without positively including them in it, are the Grenadiers (*Macrourus* of Bloch, *Lepidoliprus* of Risso). They have the muzzle depressed, and advanced farther forward than the mouth. The first dorsal high, but short; the second dorsal and the anal long, and joining the caudal. The whole skin is covered with hard scales, armed with spinous processes; and the teeth are very small. It does not appear that these fishes, the history of which is rather obscure, have any very striking resemblance to the more typical members of the cod family. They live in very deep water both in the Atlantic and the Mediterranean, but probably not so far north as even the south coasts of Britain. It is said that they make a sort of growling sound with their gill-covers when taken out of the water.

Such is an outline of this most interesting family of fishes, short and imperfect it must be admitted, but still all that our limits will afford, and, in some of the species, all that we have any data for.

**GÆRTNERA** (Roxburgh). A genus of climbing plants, natives of India and China, formerly called *Hiptage mandablota* by the botanist whose name they now bear. The flowers are decandrous, and the plants rank in the natural order *Malpighiaceæ*. They flower in our stoves, if allowed room, and are propagated by cuttings.

**GALAGO**, a genus of mammalia, belonging to the order *Quadrumanæ*, or those which have the four extremities formed for grasping. Arranged by Cuvier in the family of the *Lemuridæ*, or those four-handed animals, which have the cutting teeth in one or other of the jaws different from the apes. The other genus to which they are most nearly allied is that of the *Lovies* or slow lancers; but they differ in many particulars, and they inhabit a different locality. The *lovies* are found only in the south-east of Asia and in the eastern islands, while the *galago* belong exclusively to Africa and the islands near its eastern shore. We shall, however, save repetition, and place the relations of these animals in a clearer light by considering them along with those other genera in one general article *LEMURIDÆ*, to which accordingly the reader is referred.

**GALANTHUS** (Linnæus). The *G. nivalis* is the well-known snow-drop, of which there are only two species. It belongs to the natural order *Amaryllideæ*.

**GALATEADÆ** (Leach; or more properly **GALATHEIDÆ**). A family of macrourous ten-footed crustacea, nearly allied to the lobster family, distinguished by a broader and flattened form, by the lateral portions of the tail being formed into plates capable of opening and shutting like a fan, and by the spurious condition of the fifth pair of legs; the two anterior legs are large, and often very much flattened; the terminal segment of the tail is bilobed. The species are all marine, and some of them, although belonging to the section *Macroura*, have all the appearance of the crabs or *Brachyura*.

In the typical genus (*Galathea*, Fabricius) the tail is extended, the carapace or shell oval or oblong, rugose, or transversely striated and ciliated; the middle antennæ extended, and the claws are elongated. These crabs, or nocturnal animals, some species residing in rocky situations at a considerable depth, whilst others prefer a flat bottom at an equal depth, where they are found amongst *Algae*, *Fucus*, &c. M. Risso has published the description of a fossil species found in the excavations near Nice, which he names *Gal. antiqua*. According to M. Bosc, the mode in which the renewing of the shell is effected is very different from that which ordinarily occurs, this author asserting that it is by means of a general dislocation of all the articulations or scales of the body, together with the rapid production of intermediate plates, which become soldered to the old covering, that this is effected. We need only to refer to our article on the Crustacea in general for an account of the ordinary mode in which the moulting of these animals takes place, and which we should conceive, from analogy, must also occur in the genus under consideration.

There are two British species belonging to this genus, the names of which have been much confused by Dr. Leach. The typical species is the *Galathea strigosa* (Fabricius; *Spingera*, Leach). It is of a red colour, variegated with blue; the rostrum acute, seven-spined; the claws short, spinose, and compressed.

A third British species, *Galathea rugosa* (Fab.), forms the type of Leach's genus *Muneda*. The other genera are *Grimotea*, *Æglea*, *Calypto*, *Pisidia*, and *Porcellana*, the last of which is at once distinguished by the tail, which is folded under the body as in the *Brachyura*; the shell, moreover, is flat and orbicular, or subquadrate, and the claws triangular and nearly flat. The type is the *Cancer platycheles* of Pennant. It is found upon our rocky coasts.

**GALATHEA** (Lamarck; **VENUS**, Linnæus). This very elegant mollusc inhabits fresh water rivers. Its general character is as follows:—The shell is equivalve, subtriangular, the primary teeth furrowed, two on the right valve, joined at the base, three on the other valve, placed triangularly, the intermediate one being advanced, separate, thick, and callous; the muscular impressions are lateral, and appear double on either side. In its native state this shell is covered with a greenish epidermis, beneath which the surface is of an ivory white, highly polished, and from two to four delicately coloured violet rays, diverging from the apex to the margin, which is also slightly tinged with violet, particularly at those points of continuation of the rays which indicate the local position of the animal's excretory ducts of colouring pigment. In the arrangement of recent malacologists this shell is described as a species of *Cyclas*, to which it certainly

bears a close affinity. It may also claim an union with the genus *Cyrena*, which is now also united to the genus *Cyclas*, the distinctive characters being too finely developed to warrant a separation of the genera. Sowerby has very properly changed the name of this genus to that of *Potamophila*, *Galathea* being the name given by Fabricius (and likewise adopted by Lamarck) to a genus of crustacea. All the species of these molluscs inhabit fresh water, being located in the mud, and consequently but rarely met with in the ordinary course of seeking shells. The greater number are from India. Several fossil species have been described by Defrance and Brocchi; and Mr. Cumming, by whom malacology is so highly enriched, has discovered several species, hitherto unknown, of this genus and its congeners. In the general system we have adopted as our guide, in order to assume a given arrangement, this genus is classed in the third class *Acephalophora*, third order *Lamelibranchiata*, eighth family *Conchacea*.

**GALAXIA** (Linnæus). A genus of Cape bulbs, bearing beautiful flowers. They belong to the order *Irideæ*, and are grown in sandy loam and leaf mould, kept dry when torpid, and watered only when they are growing. They are usually kept in a frame, or in the greenhouse.

**GALBANUM** is the *Bubon galbanum* of Willdenow, a Cape of Good Hope shrub, which yields a gum much used in medicine.

**GALE**, or **SWEET GALE**, is the *Myrica gale* of Linnæus, a plant common in the northern bogs of Britain and Ireland, valued for its fine scent.

**GALEOBDOLO**N (Smith), *G. luteum*, is the yellow dead nettle of English botany, a weed common in moist shady places. It belongs to *Labiata*.

**GALEODES** (Olivier—**SOLPUGA**, Lichtenstein), a remarkable genus of arachnidous animals, forming the type of a distinct family *Galeodidæ* or *Solpugidæ*, in the order *Adelarthrosomata*, having somewhat the appearance of large spiders, but possessing a pair of large compressed claws attached in front of the mouth having the finger moveable. The palpi are large, and resemble antennæ or legs, the eyes are attached in front of the thorax, and the abdomen, which is fleshy and very hairy, is composed of nine joints. The palpi are furnished with a small organ of a whitish colour, which is only exerted when the animal is irritated. They run with great rapidity, throwing up the head in an attitude of defence when attacked, and are reputed venomous, whence the name of the typical species, *fatalis* (Fabricius). With the exception of a species found near Havanah by M. Poey, the species of this genus inhabit the hot sandy countries of the old world. Figures of some of the Egyptian species with anatomical details, are represented with the highest degree of accuracy in the great work upon Egypt, undertaken by order of Bonaparte.

**GALEOLARIA** (Lamarck). This genus of molluscs nearly approximate to the *Vermilia*, but the size of the shell, the peculiar structure of the aperture, and, more especially, the extraordinary operculum have induced Lamarck to constitute the present genus. Their tubes are found adhering together at the base in crowded groups or tufts, open at the summits; the aperture is orbicular, terminating on one side in a spatulous tongue (*lingulum spatulatum*); the operculum is squamose, furnished on the upper side with small testaceous pieces or valves, from five to nine in number, the middle one dentated at the

truncated part of its summit, the others a little toothed on their internal margin; the whole of them attached to the edge of the operculum on one side only.

**GALEOMMA** (Daudin). This shell is found in the British Channel, and one species described by Turton. It is equivalve, inequilateral, transverse, with the front margin gaping in an oval form; the hinge without teeth, and the ligament internal.

**GALEOPITHECUS**—Flying cat. A genus of Cuvier's order *Carnassier*, and the division *Cheiroptera* of that order, which division comprises only the present genus or family, and the far more numerous one of the bats. The epithet "flying cat," as applied to these animals is of course absurd, and so is "flying lemur," which has also been given to them.

As little can these animals be classed as having much resemblance to the bats, either in their external structure or in the form and arrangement of their teeth. In the bats, the toes of the fore feet are very much produced; the flying membrane is expanded on them, and there are large pectoral muscles which give them motion in the air, very inferior to that of a bird, no doubt, but still bearing a slight resemblance to it. In the animals of the present genus, on the other hand, the toes of the fore feet are not more produced than those of the hind ones; the membranes are not properly flying membranes, and there are no pectoral muscles by means of which the animals can take a stroke in the air so as to have continuous flight. In bats, though the flying membrane is often so far continued on the upper part of the hind legs, the hind feet are always free; but in the genus *galeopithecus*, the hind feet are as much connected with the membrane as the fore ones, and the intervals of the toes are webbed by a continuation of similar membrane. In the anterior part of the membrane there is also considerable difference. The head is always free in the bats, and so is the greater part of the neck. But in the present genus, the membrane extends as far forward on both sides of the head as the jaw, or even the gape. There is thus absolutely too much of the membrane for the purposes of flight—the animals are so entangled in it that they cannot by possibility fly, or take one stroke in the air with the membranes. They are thus not flying animals at all; and the membranes can answer no other purpose than that of a parachute to bring them up when they leap farther than their weight could otherwise be supported. Their whole motion cannot, however, be derived from the leap, which is at first taken from a solid point of support, and they can gain no new impetus till they alight on a second support and leap again.

From the way in which they are entangled in the membrane, it is also obvious that, while it is extended they can make no use of any part of their bodies, further than merely opening and shutting the mouth.

Any one who is in the least acquainted with the principles of animal mechanics, must at once see all this. There is no wing, or fin, or foot, or any other organ for motion of any animal, which has bones articulated to pieces of the skeleton, or of the membranes to which the organs of motion are articulated at a distance from each other. There may be many bones from different parts of the body to support the point to which the organ of motion is articulated, some very fine, instances of which will be found noticed in the article *BIRD*, and there may be any number and

arrangement of the bones in the moving part, further away from the body than this point. But the primary articulation of the organ, is always one single attachment, and the proximal part of it a single bone; and if the motion is to be a powerful one, the head of that bone is always a *trochanter*, and the joint a single ball and socket joint. There is no exception to this in any one organ of motion in the whole animal kingdom in cases where the organs are supported by bones, which is the case in all the vertebrated animals; and it would be just as impossible for an animal to move with its fore and hind legs tied together with natural membranes, as if they were tied with ropes. In the case of the bats, the hind legs have no motion in flight; for the whole of the flying membrane is put in motion on the shoulder-joint, and the only use of the hind leg in those which have the membrane extended to it, is to act as a point of support and rest. As little could these animals use the neck, by bending it in any one way which the membranes are stretched; for these brace it with equal firmness on both sides, and hold it tightly in the same position, just as the shrouds on the two sides hold the mast of a vessel. Every animal which can really fly, that is, which can take a new impulse from the air as a fulcrum, has its head, and its feet, if it has feet in addition to the organs of flight, which is generally the case, free when it flies, otherwise it would be helpless and imperfect. The same observations which have now been made apply to what are called flying squirrels, to the marsupial animals of Australia which have extended membranes, and to every animal which stretches a membrane by means of two feet on each side. Not one of them can fly; and therefore the application of the epithet flying to them is improper, as tending to mislead the ignorant.

The teeth of the *Galeopithecus*, are as peculiar as their membranes,—their mouths being the most completely insectivorous of any in the whole class of mammalia. Their cheek teeth are all tuberculated in their crowns. Their canine teeth are no higher than the cheek teeth, and they are tuberculated. They have two front teeth in the upper jaw, which are also tuberculated; and they have six fore teeth in the under jaw which are formed something like combs.

These animals are found only in the islands on the south-east of Asia, where they inhabit trees, and are rarely, if ever found on the ground. One principal part of their food is insects, of which, from the structure of their teeth there can be little doubt; another is said to be the leaves of the forest trees; and in the case of the succulent ones, this is by no means unlikely. It is, however, added by some describers that they eat birds; but this is by no means so probable,—we are not acquainted with any bird-eating mammalia, which have not canine teeth adapted for wounding, and also something in a more rearward part of the jaw which may be considered as a carnivorous tooth, of some kind or other.

These animals have five toes on each of the feet; the fore and hind feet are formed very like each other; and all the toes are articulated in the same plane, so that none of them acts against the other, or has the least resemblance to a thumb. The feet are turned laterally, and by no means adapted for walking; and, as is the case with the sloths, their most powerful action is inwards, especially of the hind feet. They can hang suspended by these feet to a

branch ; but enough of attention has not been paid to their anatomy for enabling us to ascertain whether this is done wholly by muscular effort, or whether it in part depends on an elastic ligament. They leap from tree to tree, or at least from one branch to another ; and the females—which have pectoral mamæ, carry the young partly in the membrane and partly embraced by one fore leg.

There are several museum species ; but there is not more than one real one very clearly made out. It is about the size of a cat, reddish grey on the upper part and reddish on the under ; but it is understood that the young are differently coloured from the old ones, and that they go through several differences of colour before they arrive at their full growth. They are found in the Philippines, the Pelew islands, and various other groups in the eastern seas ; but it does not appear that they occur on the main land of Asia. They are said to have a strong and unpleasant odour ; but the islanders where they are found seek after them with avidity, and eat their flesh with considerable zest. They are different in many respects from all other known animals, and not the least singular part of their history is that they are confined to so very limited a locality ; and that we have no reason to suppose that they are in any way a remnant of a race which had once been more widely distributed and consisted of more species ; for the islands which they inhabit cannot be regarded as remains of a former continent ; but are rather independent formations of more recent date than even the continent of Asia. We want more information respecting them for any thing like scientific detail.

GALERUCIDÆ, a family of herbivorous beetles belonging to the section *Tetramera*, and sub-section *Cyclica* of Latreille, and nearly allied to the *Chrysomelida* (which see, for general observations on those groups), but distinguished by having the antennæ inserted close together, and exposed at the base, the joints being sub-cylindrical, with the terminal ones generally somewhat thickened ; the body is oval, or rounded, and the palpi have the terminal joint more or less conical. These insects, which are generally of a small, or but of moderate size, are herbivorous in their larva and perfect state ; the typical species seem to prefer aquatic plants, and herbs growing in damp situations, upon which we have found some of the larvæ ; whilst others are found upon plants in hedges and fields, especially preferring the *Cruciata*. The genera are *Adorium*, *Adimonia*, *Auchenia*, *Luperus*, *Calomicrus*, *Galeruca*, and *Haltica*, with the numerous sub-generic divisions of the latter genus, which comprises the troublesome turnip-fly (*Haltica nemorum*). (See HALTICA.) The typical genus *Galeruca* (Geoffroy), comprises those species which have the legs of equal size, the hinder pair not being formed for leaping ; the antennæ with short sub-conical joints, the second being only half the length of the third ; the elytra are oval and convex. The species of this genus are rather numerous, and of dull colours. The typical species, *Gal. tanacetii* (Linnæus), being entirely black and rugose ; it is rather common, and creeps very slowly. It takes firm hold, however, upon the plants on which it is found, by means of the cushions with which the underside of the feet are furnished.—It varies in length from one-third to half an inch. There are twelve other British species.

GALIVM (Linnæus), an extensive genus of European annual, biennial, and perennial weeds, some of

which are, however, pretty, and frequently met with ornamenting waste grounds or dry banks, and familiarly known by the name of ladies' bed-straw. The *G. aparine*, or cleavers, is one of our most common hedge-bank plants, and well known from the circumstance of its seed-vessels or burs cleaving to the dress of persons coming in contact with it. It belongs to the natural order of *Rubiaceæ*.

GALLINIDÆ (poultry, and birds resembling poultry). A very numerous and well defined order of birds, consisting of numerous genera, and probably in strict systematic arrangements, of several distinct families ; but we shall be enabled to shorten our description of them, by bringing into this article the whole, except such as we have already described in the articles ARGUS, CURASSOW, and some others. In Cuvier's system, the pigeons and doves are included as a section of the order ; but they are sufficiently distinct and peculiar for being made the subject of a separate description, and we shall include them all in one general article, PIGEON, which will be found in its place in the alphabet.

In the meantime, therefore, we have to deal only with the *Gallinidæ* properly so called ; and we shall first offer a few remarks on the general characters of the order, and then enumerate the leading genera, adding particular descriptions of those species which may appear to be most worthy of attention. The legs of these birds are all formed for walking, and the upper parts are, accordingly, well supplied with muscles ; but the muscles in them are not so completely concentrated upon the legs, as they are in the ostrich family, and other birds which have no power of flight. On the other hand, the gallinidæ, though not in any case birds of long flight, are remarkable for the facility with which they can take the wing, and also descend. The peculiar structure of their wings, as adapted for the accomplishment of those purposes, will be found explained in the article BIRD ; and we shall, probably, have occasion, in the sequel of this article, to advert to some of the variations of structure which characterise particular genera or species. The front toes are mostly united at their base by a short membrane, and toothed along their margin ; the upper mandible arched, the nostrils pierced in a broad membranous space at the base of the bill, and partially covered with a cartilaginous scale. They have short wings, a heavy gait, a bony sternum, diminished by two notches, so deep and broad that they occupy nearly all its sides ; its ridge obliquely truncated forwards, so that the sharp point of the fork is united to it only by a ligament ; circumstances which, by greatly weakening the pectoral muscles, render their flight laborious. The general number of the tail feathers is fourteen, but it varies from that to eighteen or twenty. From the structure of their larynx being simple, their note is seldom agreeable. Their crop is very wide, and they have a very vigorous gizzard. Nearly the whole of the species lay and hatch their eggs on the ground, on bits of straw, or herbage carelessly put together.

In many of the genera, though not in all, the males are polygamous, each having a number of females in his train ; and as is the case with all birds which have this habit, the males fight battles of gallantry with great courage and determination, and the females, as is also the case in the other races, fall to the lot of the victor. This peculiarity in polygamous birds has never been very satisfactorily explained upon physio-

logical principles; but it should seem to have at least some connexion with the preserving of the spirit and vigour of the race. The monogamous ones do not show this pugnacity, but dwell apart and in peace with a single female, and their brood, to which in general they are much more attached than the more warlike polygamists. It is from this habit of shedding his blood for the sake of the other sex, on the part of the common domestic cock (*gallus*), that duels and strifes in the matter of females of the human race came to be called "gallantry," which again became expressive of all particular and marked attentions to the sex, and subsequently bravery in a general sense. In the polygamous species, the males take no share in preparing the nest, or rearing the young, which are for the most part very numerous, and capable of running immediately after issuing from the shell. The female guides and protects them till they moult, and calls them together by a particular cry for feeding.—The males are furnished, in most species, with spurs on their tarsi. They walk and parade very majestic and graceful, and run nimbly; but they fly with difficulty, and a whirring noise. Though they chiefly subsist on grain, and the seeds of plants, yet they likewise eat insects, grubs, and worms, which are macerated in their crop. Their gastric juice, it appears, will not dissolve entire grains; for those of barley, for example, inclosed in tubes, or perforated spherules, are not affected by its action; but, should the same grains be by any means broken, or ground, they dissolve very speedily. The food undergoes previous trituration in the gizzard, a very strong muscular viscus, whose internal coat is hard and cartilaginous. However, as this is not the sort of animal substance suited to the reception of glands, or to secretions, the gastric juice in this family is not supplied by the stomach itself, but by the gullet, in which the feeding glands are placed, and from which it trickles down into the stomach. Spallanzani, from this peculiarity of nature's economy, appears to have been struck with the resemblance between the stomachs of gallinaceous birds, and the structure of a corn-mill; for, while the two sides of the gizzard perform the office of the mill-stones, the crop, or craw, may be compared to the hopper. When our domestic fowls are abundantly supplied with food, they speedily fill their crop; but its contents do not pass immediately into the gizzard; and at all times they enter in very small quantities, in proportion to the progress of trituration.—The principal part of the species belonging to this order are very quickly, and without much trouble, tamed, and on account of their flesh, their feathers, and eggs, are very useful to mankind.

So valuable, indeed, are they in both respects, that it is doubtful whether they are more prized as domesticated, and in the species which form the ornament, and at the same time contribute not a little to the wealth of the farmyard, or in the others which are still under nature, or at most in a state of prolation, not of domestication.

The range of these birds, in the different genera and species, is greater than that of perhaps any other order in the whole class. We find them resident all the year round in the very extreme of latitude, upon the wilds of Lapland, in that dreary wilderness which forms the northern portion of America, and on the tops of the most lofty mountains in our own country. There they abide, habitually higher than any other living creature, and changing their colours, so as to

resemble lichen-clad stone in the summer, and the unstained white of the mountain snow in the winter. Then, when we come to the less elevated but more extended heath, which is still a wilderness, we find other races which make such situations their permanent abodes; and where, notwithstanding the many enemies to which they are exposed, they breed in vast numbers. So also when we come to the hollow in the wilds, the bushy margin of the wild morass, we find that it too has its peculiar race of gallinaceous birds; for there the black cock is as constant to his locality as the ptarmigan is to the summit of the lofty mountain, or the red grouse to the upland moor. As little does the pine forest lack its bird of this order; for in the vast assemblages of pine and other trees of giant growth, which fill the dells and frown over the steepes of the Scandinavian mountains, the wood grouse, one of the most splendid birds of the whole, is found in such numbers as to form a considerable article of export trade. This fine species was once native, and, according to the older accounts, not rare, in the northern parts of our island; but it has disappeared for these many years, and there is no doubt that it is now extinct. We believe that attempts have been made to introduce it artificially into the artificial pine woods, but they have not succeeded, whether from the circumstance of the bird not meeting with its proper food in these places, or from any other, we are unable to say. This much, however, is certain, that the native pines, among which the wood grouse was wont to dwell, in the Highlands of Scotland, rivalled in quality those among which it still dwells in Norway and Sweden; and that the planted pine which have come in their stead are very different and very inferior. We have heard it remarked that the planted pines, and especially the spruces, none of which, we believe, were ever natives of the Highlands, destroy the bilberry, the heath-berry, and the juniper, which are understood to furnish these birds with a considerable portion of their food; but what truth there may be in this, we have not the means of ascertaining.

When we descend to lower elevations and richer pastures, these birds still accompany our steps, and we have no sooner taken leave of the grouse at the margin of the moor, than we find the partridge on the first cultivated ground, and it continues with us till we come almost to the threshold of the rustic dwelling, to the close vicinity of the town, or to the shore of the sea; and though the quail is now rarely, if at all, resident in the British islands, we find it inhabiting still lower down; but the quail is a more discursive bird from country to country than those which we have mentioned.

All the gallinidæ which can be considered as of polar or northern extraction seem to be common to the two continents, or at all events not to differ much more than the mammalia of which the same genera are common to both; and from the readiness with which most of the birds of this order adapt themselves to circumstances, and take a type from those circumstances, we might be prepared to expect at least as great differences as there are between the grouse of the eastern continent and the grouse of America, even though both may have been originally of the same stock.

When, however, we come to the southern latitudes where the wide seas cut off the continents from each other, so that they are too distant for land birds generally, and for gallinaceous birds especially, passing

from the one to the other, we find that they are all different. Of the species which are best known as migrant birds in Europe, the greater number are from the south-east of Asia, the common country of the domestic cock, the peacock, and at least all the more gaily dressed species of pheasants. In Africa we have the Guinea fowl, and in America, the most characteristic bird is perhaps that which has been, absurdly enough, called the "Turkey," as if it had come from quite another part of the world.

All these birds of the warmer and the tropical latitudes are more of woodland birds than the majority of the northern ones; and though they all feed, and most of them nestle, on the ground, they are, generally speaking, perchers; and so strong is this habit in them that even those which have been domesticated from time immemorial retain it, and always, if they can, mount to a perch for the night.

Such is the geographical distribution of the leading members of the order; and it will not fail to occur to the reader that they are most abundant in those places of the world which are also the chief native haunts of the ruminating mammalia. Indeed, in as far as there can be a resemblance between birds and mammalia, there is a considerable resemblance between the gallinidæ and the ordinary ruminantia; and it would not perhaps be any very great stretch of fancy to trace a resemblance between the camel family of the ruminating animals and the ostrich family. The gallinidæ, like the ruminants, are all feeders upon the ground; and although the mammalia are by no means so miscellaneous in their feeding as the birds, but confine themselves more exclusively to vegetable substances, yet the birds prefer vegetable food when they can find it properly suited to their taste. There is even a coincidence between the sections of the one order and those of the other, which is too striking for being overlooked. Those of both which are most homeward, and inhabit the fattest pastures, have the flesh most tender and delicate, and the human stomach can bear it for the greatest length of time; while those which are more distant and shy in their inhabiting have the flesh of higher and more pungent flavour, but less congenial to the stomach. A person in good health could contrive to dine daily, for a long time, upon beef or barn-door fowls, but would soon tire if wholly confined to venison and grouse, or even pheasants.

There is something very pleasant, and not a little worthy both of remark and of admiration, in those natural coincidences. Those things, whether of the animal or the vegetable kingdom, which are capable of furnishing man with the most abundant, the most nourishing, and the most wholesome food, are the very ones which come, of their own nature and instinct, the nearest to the place of his abode. It is impossible not to perceive in this that there is an express provision for man in the very arrangement and system of nature; and that, if he will but take the trouble of observing and knowing all the powers and productions of nature around him, it will succeed and reward his exertions, and beacon the way to farther knowledge and more complete enjoyment.

Nor is it less worthy of attention, that there is always a corresponding beauty which accompanies utility in these matters. The orchard, the corn-field, the meadow, and the down, are associated with so many pleasurable feelings, that the very mention of them is music to the ear; and every feeling of rural

innocence, and full abundance, and beauty, and happy content, is linked with the thought of the bleating flock and the lowing herd. The poultry-yard, too, has its charms; and if there be no crowing, and cackling, and gabbling, in the neighbourhood of a farm-house, or of any residence in the country, a heavy sense of desolation comes over the mind. Neither must we despise the sounds given out by the wilder species of this order. The sound of the wings of partridges, and their soft clucking cry when they "jug" in the field, and invite each other to the common safety and the common shelter, have something delightful in them. They are sounds which are heard only in the land of plenty; and the feeling of fertility, and all the joys which it brings arise whenever those sounds are uttered.

It is not, of course, to be supposed that there can be much internal resemblance between the gallinidæ and ruminating animals, because the feeding and digestive organs of birds differ much, taken on the whole, from those of the mammalia. But there is some resemblance. The gallinidæ have, generally speaking, three stomachs, and their intestines are more lengthened than those of most birds, and furnished with two cæcal appendages about six inches in length. These three stomachs are the craw, or pouch, into which the food is taken, as into little more than a simple store, where it is sent gradually to the other parts of the digestive apparatus. In this viscus the food undergoes very little change, though it may be partially softened. This craw opens laterally from the gullet. The second stomach is a dilatation of the gullet itself, and is furnished with glands which secrete a peculiar fluid; and it is here also that the drink of the birds mingles with the food. The third stomach is the gizzard, the texture of which is very strong and muscular, and the inner coat so hard and compact, as to have the appearance of firm cartilage. This viscus can exert a very powerful action, so powerful as to grind down glass and metals in a very short time, without appearing to sustain any injury. It is into this part of the structure the small stones and gravel are taken along with the food. The precise office which these perform in the digestion of the animal is not accurately known, but there is every reason for believing that it is very important; for it has been ascertained, by actual and repeated trial, that some of the order, the pheasants, for instance, can thrive as well on half the quantity of food, when they have free access to gravel, that they require when they have no such access. The inference of course is, that the gravel must, in some way or other, double the digestive powers of the bird, inasmuch as they enable it to draw equal, or even superior nourishment, from only half the quantity of food, but those assisting matters never substantially add anything to the nourishment. We have, however, already alluded to Spallanzani's somewhat whimsical comparison of this gizzard to a corn-mill, though it does not exactly hold, as the gizzard, which may be considered as the one mill-stone, grinds the others as well as the food, and the gastric juice afforded by the glands of the second stomach is mixed with the food before it reaches the gizzard; so that, if the action of it is a grinding action, it is not "dry-grinding," but rather resembles beating, or kneading in a mortar, along with a solvent fluid, which aids in rendering the harder substance.

We shall now very shortly mention the general

arrangement of these birds. Cuvier makes seven families :

1. **ALECTORIDÆ** (*Alectoridæ*), of which we have given some slight notice under that title. Of this family there are four genera; Curassows (*Crax*), which have been already noticed; Pauxi (*Ouarx*); Guan (*Penelope*); and Parraqua (*Otialida*).

2. **OPISTHOCOMUS** (the *Hoazin* of Buffon), of which there is but one species, and very little is known of it.

3. **PEACOCKS** (*Pavo*), forming two genera, the peacocks properly so called, and *Lophophorus*.

4. **TURKEYS** (*Meleagris*).

5. **GUINEA FOWL** (*Numida*).

6. **PHEASANTS** (*Phasianus*), of which there are four genera: Common Fowls (*Gallus*); Pheasants (*Phasianus*); Houppijera, *Tragopon*, and *Cryptonix*.

7. **GROUSE** (*Tetrao*), of which the genera, and also the species, are much more numerous than in most of the others. As it would exceed our limits, and be inconsistent with the plan of this work, to go into all the details, we shall advert most particularly to those that possess the greatest interest; and, for this reason, we shall begin with those that may be considered as most typical of the order, and, at the same time, of most value to man.

**GALLUS.**—The common Cock, or common domestic poultry. This is the genus from which the order is named, and must, therefore, be considered as the typical one; and it is so well known as not to require much description. The most general characters of the male bird are, a fleshy crest on the crown of the head, which usually consists of a single pectinated lamella, or plate, which is called the "comb;" but it is sometimes double, or even formed into a kind of rosette. The sides of the base of the under mandible are also each furnished with a pendent lobe, of the same appearance and texture as the crest, and these are called "wattles." When the bird is in "prime feather," these appendages are of a bright crimson; but when moulting, or otherwise in bad condition, they are pale; and when the bird is exposed to severe cold, they are purple or bluish. The tail consists of fourteen feathers, seven on each side, which fold backwards against each other, like the leaves of a book, when the bird is on the ground or in a state of repose. The tail-coverts are much produced, and hang over the tail feathers in very graceful arches; and they are often richly glossed with metallic reflections of bronze, purple, or green. The feathers on the neck are also very much produced and pointed. These feathers are called the "hackle." In a state of repose, they form a mantle on the neck and upper part of the shoulder; but when the bird is excited and shows fight, they are erected, and break the force of any stroke aimed against that part of the body. All the varieties have a naked space on the cheeks and round the eyes, which is of the same texture as the comb and wattles, and varies in colour in the same way. This character belongs to the female as well as the male; but in the female the crest and wattles are merely rudimental, excepting in some individuals which have become barren, and they acquire a sort of neuter appearance, intermediate between that of the male and the fertile female. The male is furnished with a horny spur on the tarsus, which is his weapon of war; and this, which is only rudimental, if at all visible, in the fertile female, sometimes appears in those that have become barren. When the female

has put on any of these appearances of the male, it may always be concluded that her barrenness is confirmed, and that she has ceased to be useful in a domestic point of view.

It would be in vain to attempt any description of the varieties of common poultry, as they occur in a domestic state. But though they have been familiarly known and very abundant in all parts of the eastern world pretending to any degree of civilisation and domestic economy, ever since, and even before the earliest historic records, it was long before any knowledge of their native country was obtained. Inured to almost every climate, from the greatest heat to the most intense cold, they appear to have accompanied the human race in all their migrations; and as they are remarkably obedient to circumstances, even to those that are too minute for being observed by mankind, they take a type from countries, and even from districts. They vary much in size, and their tints and shades of colour are endless. Some have the tarsi bare, while others have their feathers down to the division of the toes. In some, the crest on the top of the head is replaced by a tuft of feathers, which is often very handsome; but in some of the varieties, these feathers grow so long as to hang down over their eyes and obstruct the vision of the birds. Some have the comb and the wattles quite black, and when this is the case, the same colour extends to the periosteum, or membrane covering the bones, in all the skeleton. There seems to be a remarkable susceptibility to colour in the periosteum of these birds, which is soon communicated to the substance of the bones; for when dye-stuffs are mixed with their food, the tint of the dye tells upon the bones. In many of the varieties, too, there are monstrous productions of the feet. Thus, for instance, a fine breed which are met with chiefly in the county of Surrey, and known as "Dorking fowls," have five or six toes upon each foot. This formation is not, however, confined to that particular breed, but occurs in probably all breeds, for "a ten-toed hen," is an expression known in many parts of the country; and in the witching times, when charms and counter-charms were in repute, and all singular productions of nature were called in to help in the matters of weal or woe, the ten-toed hen had her use, much in the same way that the crowing of the cock was understood to send quietly to their repose in "the Red Sea," during the day, those spirits of nocturnal fear which ventured to walk the earth when the clarion-sentinel of the village was slumbering on his perch. Absurd as these matters are in themselves, they suffice to show the interest which our ancestors took in those birds; and, indeed, there is no animal which makes a more conspicuous figure in ancient history and fable than the common cock. His beauty, his bravery, his usefulness, and, as much as anything, his cheerful and early call, when the grey of morning has barely streaked the east, all conspire to render him one of the most interesting of birds. We give the following quotation from Pliny, as a specimen of the opinions of the ancients: "Next to the peacock," says he, "the birds which are most sensible to glory are those active sentinels which nature has produced to rouse us from our matin slumbers, and send us to our daily occupations. They are acquainted with the stars, and every three hours they indicate by their crowing the different periods of the day. They retire to repose with the setting sun, and from the fourth mili-

tary watch they recal us loudly to our labours and cares. They do not suffer the day-beam to surprise us without timely warning. Their crowing announces the hour of morning, and the crowing itself is announced by the clapping of their wings. Each farm-yard has its peculiar king; and amongst these monarchs, as amongst princes of our race, empire is the meed of victory. They appear to comprehend the design of those weapons with which their feet are armed. It is not uncommon for two rivals to perish in the combat. If one be conqueror, he immediately sings forth his triumph, and proclaims his own supremacy; the other retreats and disappears, ashamed of his defeat. The gait of the cock is proud and commanding; he walks with head erect and elevated crest. Alone of all birds he habitually looks up to the sky, raising at the same time his curved and sithe-formed tail, and inspiring terror in the lion himself, that most intrepid of animals. Some of these birds seem actually born for nothing but warfare and battles; some have rendered the countries which produced them famous, such as Rhodes and Tanagra. The second rank is assigned to those from Melos and Chalcis,—birds truly worthy of the homage they receive from the Roman people! Their repasts are solemn presages; they regulate daily the conduct of our magistrates, and open or close to them their own houses. They prescribe repose or movement to the Roman fasces; they command or prohibit battles; they have announced all the victories gained throughout the universe; in a word, they lord it over the masters of the world. Their very entrails and fibres are not less agreeable to the gods than the richest victims. Their prolonged notes in the evening, and at extraordinary hours, constitute presages. By crowing all night long they announced to the Bœotians a celebrated victory over the Lacedæmonians; thus did the diviners interpret it, because this bird never crows when he is conquered."

The cock is more stately in his march than any bird, or, indeed, than almost any animal. His tread is slow and firm, his step long, and his whole frame expressive of energy and vigour. The eye of the cock is lively and animated, his air proud and independent, without anything ferocious or menacing. He is a being confident in his own strength and courage, conscious of his own worth, but not disdainful of others. Sure of his own superiority, and of the right which he assumes, he knows how to maintain them in everything of importance, and how to relax in matters of less consideration. Though the cock reigns and rules like a bashaw over his harem, yet he is an attentive husband and a tender father. The females and their young are to him a people that must obey, but they must at the same time be governed with mildness. Their weakness and his strength secure submission on the one hand, and protection on the other. He desires no food for himself but as much as will suffice to support his strength; and should he chance to meet with anything delicate, he touches it not, but calls his family around him, who answer immediately to the voice of their master who summons them, and of a husband and father who invites. His acquisition he shares between the mothers and the children, answering to their murmurs of gratitude by lower and gentler accents. His progeny are protected by his acting either on the defensive or offensive against every enemy that assails them. He repels and combats with all intruding animals. And acts as

a master with the other birds of the poultry-yard, and compels them to keep at a respectful distance from his establishment. But his greatest wrath and irritation he exhibits against one of his own sex and species; he will contend with him until his adversary retreats by flight or is destroyed, or his own strength fails. He claps his wings, if successful, and utters several shrill and reiterated crows, in token of his success.

From the cock being of a warm and vigorous constitution, one will suffice for fifteen or twenty-hens. To those, however, who are engaged in the breeding of poultry the choice of a cock is of great importance. He is judged to possess all the necessary qualities when he is of a fine shape, but middle size; when he carries his head boldly and erect, has a quick, lively, and animated eye, a powerful and clear voice, and a thick and short bill. He should have a bright and polished red comb, a membranous wattle, of considerable size, and equally high coloured with the crest. The wings should be strong, the chest broad, the plumage very dark red or black, the thighs very muscular, the legs stout, and armed with long spurs, the toes provided with claws slightly crooked, and strongly acerated. He should also be alert and petulant in his demeanour, as well as prompt in defending the females; attentive in soliciting them to eat, in keeping them together during the day, and assembling them in the evening for rest.

At the age of three or four months the cock has arrived so far to maturity as to be able to propagate, which lasts in perfection four or five years, though he may live to the age of ten, and in some rare instances to fifteen years. The larger species and varieties of cocks are more slow in their development, and their prime, in all probability, lasts longer. When the cock becomes aged he must be turned out of the farmyard, as no longer worthy to figure there, and a young and vigorous one placed there in his stead. When the poultry-yard is divided between two or more cocks, peace reigns but a short time among them. Their jealous and impetuous character soon breaks out in frequent and bloody quarrels, combat follows instantaneously on provocation; the two adversaries stand opposed to each other with erected plumes, keeping the neck extended and the head low; with fixed and sparkling eyes they observe each other in silence; on the slightest movement from either they erect themselves, dart upon, and tilt their bodies against each other: this manœuvre is repeated until the most adroit and the strongest has torn the comb of his enemy, and overwhelmed him with blows from his wings, or gored him with his spurs. Some cocks are of a very quarrelsome and peevish disposition, they beat and annoy the hens, and are continually disturbing the establishments of their neighbours. The most simple method of quieting these refractory subjects is by passing a piece of leather over the foot, close under the spur; they then become as quiet as men who have got irons on their hands and feet. The cock is a very clean bird, is careful of his dress, and may frequently be seen engaged in cleansing, combing, and polishing his feathers with his bill. If, like the warbler or the nightingale, whose melody is created by love, he has no ambition to be distinguished by the excellence of his music, it is certain that he is very fond of exhibiting the strength, the sonorousness, and the compass of his voice. He listens after crowing, to hear if he is answered, and should another cock reply he recommences immediately, and appears

to defy him to raise his voice higher than his own. This emulous cry, repeated by all the cocks of a village, on an obscure night, has often struck the ear of the wandering traveller, and proved the happy means of directing him to the right road. It is very generally imagined that the cock is not designed by nature to share in the solitudes of incubation and the education of the young; but on a little more closely examining matters, we are forced to relinquish this opinion, at least as a habit to which there are no exceptions.

This leads us to a remarkable peculiarity in the physiology of these animals. It has been known from very remote antiquity, that changing the male bird of this species into what is called a capon, by depriving him of his sexual powers, greatly improves the quality, and even the quantity of his flesh. This is general in the case of mutilated male animals, provided the mutilation takes place at that early period of life when the external indications of sex have not yet displayed themselves, and the bird is in that state which may be regarded as neuter. The change which the female undergoes in respect of quality of flesh when it arrives at maturity, is not in any species of animal so great as that in the male; but still there is a change, and the flesh of the female is neither so good nor so abundant as that of the mutilated male. By preparing the capon at this early stage, and before any decided sexual character is acquired, the flesh is secured in the best condition, and the operation is performed with little or no risk.

Now, the remarkable physiological part of this business is, that the capon acquires so much of the disposition of the female, that he may be made to attend on young chickens, and watch and nurse them with all the solicitude of a hen. Experiments on this subject, which were made some time ago in France, are detailed by M. Parmentier, who mentions that capons have been trained not only to attend chickens, but to hatch eggs, an office in which the entire male bird never takes any concern. A strong and active capon is chosen for this purpose; the feathers are removed from the belly, he is rubbed with nettles, and made intoxicated with toast and wine. For two or three days this treatment is repeated, during which they keep him shut up in some narrow and confined place; he is then put into a cage with two or three chickens, which feed with him, hide under his belly, and, by their down, calm the smarts which the pulling of the feathers and the nettles have occasioned. He grows attached to them in a very short time, and calls them back when they quit him. Their number is augmented daily until he has as many as the volume of his body and the amplitude of his wings will cover. As soon as the intended number is completed, he must be left two days longer with them in a large cage, and then permitted to proceed forth conducting his flock, and he will prove as careful and attentive to them as the most assiduous female. Capons do not undergo the annual change in their plumage as other birds. Their voice loses its strength and clearness; they seldom attempt to make it heard, and are very melancholy and sad in their disposition. They are treated with great severity by the cocks, and they are held in detestation by the hens. They would very speedily fall a sacrifice to the persecutions of their companions, if they were not withdrawn to fulfil the object of their destiny by man, who has degraded them for his own purposes! This object is simply to

eat, drink, and sleep, that they may get fat as soon as possible for the use of the table, as they themselves can have no enjoyment in the matter. Sometimes hens are caponed as well as cocks, and the flavour of their flesh is very much improved in consequence. The epicurism of man has suggested various modes of fattening fowls excessively, all which are unnatural, and more or less cruel. The result, in fact, is always to produce disease, and more particularly of the liver. All those artificial modes of forcing animals into unnatural states either of general fat, or of the growth of some particular organ, are the results of vitiated tastes, and were more common in the dark and barbarous ages than they are now. There is a law which runs through the whole economy of those living creatures which are used as human food, and from that law there appears to be no deviation. It is this: No animal can furnish healthy food for man unless it is itself healthy at the time when it is prepared as food. Hence, those who violate this law, and seek to gratify a depraved luxury by bringing on disease in that which they eat, certainly lay, in this misguided sacrifice to the lowest of their animal appetites, a sure foundation for disease in themselves, and bitter repentance when it is too late.

In many parts of the world, especially in Egypt, and partially in France, and there is no doubt that it could easily be practised in any country, chickens are hatched by artificial heat in ovens, and reared by human care. This is so perfectly artificial a matter, that it forms no part whatever of Natural History, further than as it shows that after the mature egg is dropped, the real labour of the parent-bird is at an end; and that both substantively and actively, in so far as the egg is concerned, it contains all that is requisite for the development of the new being, and wants only the action of *any* heat, of the proper degree, to bring it to maturity. As this is, perhaps, the only opportunity which we may have of adverting to the progress of the development of the young of a bird, which is a curious matter, we shall here take a very rapid glance at it.

The germ, or as it is called, the *cicatricula*, in the recent egg, and before incubation, is very small. It is placed on the surface of the spheroid of the yolk; and, by a peculiar structure of the egg, it always keeps the upper side, in what situation soever the egg may be placed. The white of the egg is much less susceptible of putridity than the yolk, or rather than the membrane in which the yolk is enclosed; and if, from the egg's lying long in one position, the yolk descends till the membrane comes wholly, or very nearly into contact with the shell, an action is apt to be excited in the membrane, different from the living action that commences in the *cicatricula*; and as every action in a living body or a germ of life, be it of which kind it may, which is not a living action, is an action of death and putridity, the life of the egg may be destroyed by this means; and it may give out that odour of sulphuretted hydrogen, which is so very noxious. This may happen in the process of hatching, as well as in an unhatched egg; for if the action of the membrane is too much for that of the embryo chicken, the life may be extinguished at the very time that it is just beginning to develop itself. Hence, hens, especially in the earlier stages of their sitting, are observed to turn their eggs, or if they do not this, the chance is, that some of the number will be added and produce nothing.

The point which indicates the germ in the egg, is very properly termed the *cicatricula*, "the little union," for the real germ is then so small, that it does little more than indicate that there is in the egg, the union of a rudiment of life to be nourished, and a nourishing apparatus to bring it forward. There is thus some resemblance between the contents of the egg and those of the internal uterus of a viviparous animal when gravid. The living part is fœtal, and the nourishing part is placental, in the one case as well as in the other; and there is the same double membranes, the same mysterious confine which both unites and separates, in the one case as in the other: and when pulsation begins, it is not the same in the vessels of the placenta and those of the chicken, any more than it is in the case of an uterine mother. This is the nice point, and could we see the first throb of elementary action here, one of the most marvellous of nature's secrets would be in our possession. But here there is a veil, behind which it is not given to mortal eyes to look. "Is the first impulse given by the placenta to the embryo, or by the embryo to the placenta?" This is the grand question, but we cannot answer it.

The case of the egg is far more wonderful than that of the living mother in placental connexion (or must we limit the expression to juxtaposition?) The egg may be carried to a long distance; it may be hatched in an oven, under another animal, by any heat indeed; and there is a tolerably well authenticated story of a tailor, who hatched the egg of a goose under him on his shop-board, and thus was in possession of "a tailor's goose that could fly;" and the especial wonder is, that the mother should be able to deposit the faculty of maturity in the egg along with the germ of the chicken. Truly this same egg is a wonderful thing; there is more in it than in all the products of wisdom and skill which man ever made, or ever can make. But we cannot afford to dwell upon it even in contemplation. The reader may—and should.

At the end of about twelve hours after the incubation commences, the *cicatricula* begins to act, slowly to appearance at first, but more rapidly afterwards, though the first start is the grand point in the progress. After there is an action begun, we can conceive how it may go on, because the elapsed time, however short, gives us a judgment of experience upon which to anticipate the future; but a *beginning* is a mighty mystery.

The parts develop in succession, some earlier than others, but they are at first all apparently formed of gelatine, though the predominating matter in the egg itself is albumen. The progress of growth is so slow and gradual, that it is not in itself an object of observation; indeed, growth is thus far like life, that we can see it only in its effects. The vertebral portion of the chicken is the first that we can trace, which we can do in that which is to be the head, and also the spine, even on the first day of action; and this is a direct proof that vertebrated animals are really, in the order of time, organised upon the spine, which points strongly to the brain, and its continuation in the first predial of the action of young life, though we are unable to regard the point as altogether settled. On the second day the vertebræ show rudimental existence, and about the same time the heart, as the centre of the vascular system, begins to be formed, clearly proving that that system is secondary and subordi-

nate to that whose centre is the brain. The neck and breast are formed on the third day; and the eyes and liver are formed on the fourth. The stomach and veins are formed on the fifth day; and the lungs and skin on the sixth. On the seventh the bill and intestines are formed; and on the eighth the ventricles of the heart and the gall bladder. On the ninth the thighs and wings are formed, and on the tenth the whole of the parts which constitute the chicken are in their places, and have already assumed the form which characterises them. They are developed still more on the subsequent days, acquire all the growth of which they are susceptible in this state, and the chicken becomes sufficiently strong to break the shell, which takes place after the lapse of three weeks. The principle of life introduced by the act of the male into the egg already commenced in the female ovary, most probably contributes to organise it for the end which nature has purposed. But immediately after this egg is laid the principle of life slumbers in it, until awakened by the caloric communicated by the sitting hen; it then in connection with this last agent, gives motion to the embryo which it is commissioned to animate. It communicates to it the faculty of increase, of employing in its organisation and nutriment all the substances which are enclosed with it in this isolated matrix, which, however, fulfils all the same functions as those of the mammalia. The yolk of the egg then augments in quantity at the expense of the albumen, the fluid part of which it absorbs. It becomes a nutritious milk, which is carried into the liver, elaborated there, and finally passes into the circulation. To the nineteenth day of the incubation, the yolk forms in the egg a distinct body from the chicken shut up in a separate capsule. The only communication which they have together is by vessels which hold the place of the umbilical cord; but it is introduced altogether on the nineteenth day into the abdomen, and so increases by its presence the volume of the chicken, that there is not sufficient room afterwards for it in the lymphatic bag where it was. It then bursts and the pulmonary organs come in contact with the air, which has penetrated into the egg, to fill the space occasioned there by evaporation. The chicken respire, whines, its vital force acquires more energy, it moves, its limbs are developed, its bill is brought into action, its shell is broken, and it then issues forth.

In all those places of Europe where the temperature is at all moderate, the common hen produces a great number of eggs in the course of the year; but always the more if properly attended to in proportion as the climate is warm. In the extreme north, as in the northern parts of Siberia, in the very extremity of Lapland, and in Greenland, and of course in the very north of America, they do not breed; but considering that they are originally from Judea, they have a remarkable range of climate. In order that the produce of a hen in eggs may be the greatest possible, she should have abundance of wholesome food, but not be fattened beyond a certain extent, for the eggs of over-fat hens are both few and imperfect. The hen should be placed in a situation rather warm and sheltered, have access to cold water and to gravel, and be allowed plenty of exercise, but in no case alarmed or driven when treated in this manner. A hen of a good breed will furnish about two eggs every three days, and if not allowed to sit, she will continue with little intermission for ten months of the

year, that is to say, in the course of this period she will produce about 200 eggs. No hen can rear above one-tenth that number of chickens, which shows the advantage of those artificial means of hatching which are resorted to in countries where human labour is not too valuable for being devoted to such purposes.

Numerous conjectures have been formed as to the species of India, which is the parent stock of the common fowls; but these are, of course, very vague, and indeed the wild ones are almost as much varied in the different parts of the south east of Asia, and the eastern islands, as the tame ones are in Europe. Temminck is of opinion, that the common domestic breed (some of the more striking varieties are understood to be from other sources) are hybrids, between two species still found in the eastern islands, and which agree more in the females with our domesticated ones, than is the case with any others of the wild ones. There are the Jago cock found in Sumatra and Java; and the Bankiva cock, found in the woods of the latter island. In both of these the females have rudimental combs and wattles as ours have, and this is said not to be the case with the other wild ones.

THE JAGO COCK (*G. giganteus*) is at least double the size of the common cock of Europe, with the comb and wattles red, as in the common cock. The colours are rich, not unlike those of the finer specimens of the common one. It stands very high on the legs, and marches in a very stately and majestic manner. The Europeans in India, call this magnificent species the *Kulm cock*, but the common belief in India is, that it is not indigenous in that country, and we believe that it is not found in the wild state there, unless under circumstances which lead to the conclusion, that it had strayed into the woods, as animals are apt to do in such climates. Some of these great cocks are highly valued as game birds; and the true game are known by having the irides white or pale straw yellow. A cock of this variety in the possession of Colonel Sykes, stood twenty-six inches in height, and measured twenty-three inches from the point of the bill to the insertion of the tail. The hen is a third smaller. When tired, this species rests itself on the first joint of the leg, in which position it is as high as the common species. Colonel Sykes brought a hen and two cocks to England in 1831. They bore the voyage and the climate very well, and by September, 1832, the hen had reared two broods. There is not the least doubt that they would agree with the climate of Britain quite as well as the common variety; and it is known that they have for some time been introduced into different parts of Italy and France, where they have succeeded very well.

THE BANKIVA COCK (*G. bankiva*) is a much smaller species, only about ten or eleven inches from the point of the bill to the insertion of the tail. The feathers on the nape, the neck, the back, the coverts of the wings, with the exception of the greater ones, are of a purplish maroon brown; the greater coverts of the wings black, with metallic reflections; the tail-coverts long, arched, and of a yellowish colour, with bright metallic reflections of reddish, the quills of the wings black, margined with red; and all the under part black, with metallic reflections. The naked parts red, of a bright tint; the bill and feet grey, and the irides of a straw yellow.

THE BANTAM COCK (*G. pusillus*) is originally from the same parts of the world with the Bankiva cock;

resembles that one much in size, and is supposed to be a mere variety of it, inhabiting more elevated places, as it is found in the allied genus of the pheasants, that the mountain species even under the equator, and where they are understood to perch for the night, have the tarsi feathered, which is the chief external distinction between the Bantam cock and the Bankiva. The exterior sides of the tarsi in the Bantam are covered with very long feathers, which reach down as far as the toes. The Bantam thrives well in a state of domestication, and is a valuable little breed, the male being exceedingly bold and pugnacious in proportion to its size.

THE JUNGLE COCK (*G. Sonneratii*) is very abundant in the woods of the higher jungles in the south of India, especially in those of the Western Ghauts on the Malabar coast. There are two species or varieties. The one is long-legged, and inhabits the thick woods in the mountain valleys, to the height of about 2000 feet above the level of the sea. The comb is very much toothed, the lower mandible furnished with wattles; the feathers of the neck produced, and spotted with white, furnished with membranous or cartilaginous tips, which appendages occur also in the female. Along with the white spots, these feathers in the male are mottled with black and dull reddish brown. The breast, abdomen, and back, are grey, streaked with white; the coverts of the wings are reddish chestnut, with the feathers terminating in cartilaginous discs of a fulvous colour; and the quills and tail-feathers are deep black. The female is smaller than the male, and is wholly destitute of the comb and wattles. The head in this sex is completely covered with feathers, and the colours of the body are duller, and marked with brown and red. This appears to have been the first species or variety which was found very abundantly in the wild state in the woods of India, and hence it was considered as the parent stock of the domestic fowl; but the difference in the primal, and the first (we believe) of this species being rarely domesticated in India, are against the supposition; and if the parent stock is still to be found in that country, it must in all probability be sought in one, or other, or both, of those to which Temminck has referred it.

It must not be forgotten, however, that the common fowl apparently is a distinct species, and in many varieties, is, perhaps, more abundant in India than in any other country. In those parts of the country where there are few Europeans, they can be bought for about twopence each. They often resemble the jungle fowl in colour, but they are uniformly without the cartilaginous discs on the feathers of the neck and coverts.

The other variety of Indian wild fowl is found in nearly the same localities, but at a much greater elevation, occurring in the scattered plantations as high up as 4000 feet above the level of the sea. The male in this one has a great deal of red on the plumage; and the female is brownish red, and without any cartilaginous spots. The eggs are shaped like those of the common fowl, but smaller in size; the crow and call of the cock have no inconsiderable resemblance to those of the Bantam.

THE NEGRO COCK (*G. morion*) is very probably nothing more than an accidental variety, at all events it is met with only accidentally. The comb and wattles, and also the skin and periosteum are quite black; and this gives the bird a dull and rather un-

sightly appearance; but the flesh is quite as palatable and wholesome as that of those which have the most gay and brilliant colours.

THE FORK-TAILED COCK (*G. furcata*). The chief peculiarity of this species or variety is the form of the tail, which is not folded the one half upon the other, as in most of the species, but flattened and forked at the termination. This is a native of Java, and the Javese give it a name different from any others of the genus. The feathers of the nape and neck are brown at their bases, blue with purple reflections in the middle of their length, and golden green, dotted with black, at the points. The feathers on the back are also brown at the base, but the rest is blackish, with gold coloured reflections, and the extremities margined with brownish yellow; the body of the feathers on the wing-coverts resembles that on those of the back, but the margins are bright red; the quills are blackish brown, and the tail feathers golden green; the crest is entire in the margins, and there is only one wattle under the lower jaw; these, and the other naked parts of the head, are bright purple; the feet and irides are yellow, and the spurs upon the tarsi are very sharp. The length of the male bird, including the tail, is about two feet; that of the female does not exceed fourteen inches. The female has no vestige either of comb or of wattle; the naked skin round the eye is reddish yellow; the top of the head and the neck are brownish grey; the upper parts are blackish golden green, streaked and spotted with greyish brown; the throat white, the under parts brownish ash; and the quills brown, bordered with reddish.

Those which have been enumerated are only a few out of the countless numbers that have been figured and described; but the birds are so prone to break into varieties, that there is no depending upon a single specimen, or even upon several specimens, for the establishment of a species, or even of a variety, except a merely accidental one, which may break out in one as well as in another. Nor shall we go into any enumeration of the varieties of the domestic breed that are generally described. The habits of the whole genus *Gallus*, indeed, so much resemble each other, that the account of one may answer for the whole. There is, however, one result of their proneness to sport varieties, which may be worthy of some slight notice, and that is the monstrous formations which they sometimes assume, and which appear to be more singular than those of almost any other race of animals. "In 1802, a Jew exhibited for money, at Posen, in Poland, a hen with a human face, which was hatched in a farm near Wryesnier, and which he had received in payment of a small debt. He declared that another chicken, altogether similar, had been in the same brood, but that it died soon after its birth. The animal which he exhibited, and which I have myself seen, was alive, and in excellent health. It had attained its full size, for it was more than a year old. Its body was covered with feathers of different colours, and it resembled other hens in every respect, except the head; this was of the usual size but denuded of feathers, and covered with a bluish skin. The cavities of the eyes were completely like those of human eyes; they were surmounted by two small arches of down, which formed very regular eyebrows. The upper part of the bill was shorter than usual; it had but one blunted point, and the nostrils were underneath it, so that, although it was horn, it presented the perfect resemblance of a very

well-made nose; below this nose was a very regular mouth with lips; two rows of very white teeth, close and pointed, and a rounded tongue, completed this most extraordinary *lusus nature*. This resemblance to a human countenance had something in it extremely disagreeable, and even horrid; but was perfect, and had no need of the assistance of imagination to be recognised." The Gazette de Santé, in the year 1810, published an account of another phenomenon of this kind. But the resemblance to a human countenance was not quite so perfect as in the last, yet was nevertheless very obvious. The writer of the article says, "The place where the bill should be presents a human profile, resembling that of an old woman; the bill is entirely wanting; the jaws are shortened, so as to terminate in a point where the nostrils are placed in other hens; they are covered with flesh, and resemble lips. The crest, on a face view, forms a kind of nose, so much the more remarkable as the nostrils are placed at the point where this nose terminates, and are united to the jaw. A fleshy excrescence, not seen in other hens, is attached below the under jaw, and represents a sort of chin; this chin is naked, with the exception of a few hairs, and the naked skin which forms it is prolonged as far as the ears, as in the common hen. The eyes are round and black, and surrounded with an iris of a very lively red. Under the eyes the skin is flesh-coloured, mingled with blue, and naked, with the exception of a tuft of hairs, forming a kind of mustachio towards the ears, and concealing the apertures." Many other instances of a similar kind are recorded; but those which we have quoted must suffice as a specimen, the more so that they are mere curiosities, from which no useful conclusion can be drawn.

PHASIANUS—Pheasant. This is a very interesting genus, most of the members of which are alike remarkable for the elegance of their forms and the beauty of their plumage. They are not by any means so social as common poultry, and none of the species can be said to be in a state of complete domestication. They are nearly allied to common poultry, so much so that when domestic hens become wild in parks, which they often do when they have free range in large ones, they produce hybrids with the common pheasant; but whether these hybrids can breed with each other, as is the case in crosses with mere varieties of the same species, or only back to the pure blood, as is the case with mules between different species, has not been ascertained in a satisfactory manner. In this case, however, as in all similar ones, it is the domesticated female and the male in the wild state that produce the hybrid; and we believe that there is no instance of one between even one of those domestic cocks that become wild in the woods and a female pheasant. Nor is it understood that the hens go astray after other lovers in the wild places until the males of their own race are gone.

The leading characters of the pheasant genus are: the bill rather short, but thick and stout, naked at the base, and bent down at the tip. The nostrils lateral at the base of the bill; the ears covered with feathers; the feet with four toes, three to the front and one behind, fitted for walking and for scraping the earth, as is the habit of many of the order; the tarsi of the male furnished with spurs as in the common cock, the tail lengthened, wedge-shaped, and composed of as many as eighteen feathers, which are in some of the species very much produced. The wings are

short and hollow; and though the birds are much better fliers than common fowls, especially when these are in a state of domestication, their flight is heavy and fluttering, and apparently produced with considerable effort.

All the known species are natives of Asia, and they are inhabitants of woods or wooded places, where they perch in trees during the night, but they feed and nestle upon the ground. As is the case with most of the order, their nests are very rude and hardly deserving the name. The broods are numerous, but the numbers vary a good deal with the characters of the climate. The young, when they first make their appearance, are covered with soft down; and they can run and pick up their food almost as soon as they break the shell. There are several species and varieties of pheasants, besides hybrids between the different ones, and between the male and other gallinidæ; and though in general they are, as wild birds, more constant to their colours than domesticated birds, there are often coloured varieties, and even albinos.

THE COMMON PHEASANT (*P. Colchis*) is so called from the country whence it is said to have been first brought to Europe, which is generally understood to have been from the banks of the river Phasis, in the ancient state of Colchis, or the modern province of Mingrelia. They are now, however, pretty generally introduced as ornamental birds into all the more warm and temperate parts of Europe; and on the continent they are found as far north as the countries adjoining the northern bay of the Baltic, and in Asia as far as Siberia. In all places where they are found, their appearance and their flesh are both highly prized, but they cannot be considered of much value in an economical point of view, as they can hardly be said to be in the possession of the real cultivators of the ground, and breeders of domestic animals for economical purposes. It furnishes our tables with a very delicate article of food, and adorns our parks and thickets, which it greatly enlivens. From its having short wings, it flies rather heavily, and to a short distance at a time. It is with difficulty tamed, being naturally very shy, living in a very solitary manner, and, except in the pairing season, it seems averse to consort even with those of its own species. Yet when these birds are in the constant habit of being attended in the coverts by a keeper, they will immediately attend his whistle to be fed; nay, will follow him in flocks, and will scarcely allow the peas to run into the trough before they begin to eat; and those that cannot find sufficient room at one trough will follow him with the same familiarity to another. They are fond of buck-wheat and corn, but will frequently feed on the wild berries of the woods, and on acorns. They feed their young on insects, worms, and the pupæ of ants. They are fond of the shelter of woods and thickets, but will very frequently breed in clover fields. The nest is made on the ground, and is generally composed of dry vegetables very carelessly put together. The female endeavours to conceal it from the male, and lays from ten to sixteen eggs, which are somewhat smaller than those of the common hen, and of a greenish grey colour spotted with brown. The incubation lasts rather more than three weeks; and as soon as the young break the shell they follow the mother like chickens. Should they not be disturbed, the parents and their brood remain in the hedge-rows and stubble for some time;

but if molested or scared, they will quit those places and betake themselves to the woods, and come forth only to feed in the morning and evening. In a confined state the female neither lays so many eggs nor hatches and rears her brood with so much care and vigilance as in the fields. In a mew she will rarely dispose her eggs in a nest, or sit on them at all; so that the domestic hen is usually entrusted with the charge of hatching and breeding the young. The female pheasant is less careful in calling her brood together than the partridge, even when enjoying greater freedom; but she will shelter as many as seek protection under her wings. After all, about one-third of the young race never attain to full growth; for many fall a sacrifice to the first moulting, and several to a disorder which proceeds from the presence of a species of fasciola in the trachea called "oscitans" or "gapes." A very considerable number of their eggs is sometimes destroyed by the mowing of clover near woods which pheasants frequent. As the cold weather approaches, these birds begin to fly at sunset to the branches of the oaks, which they roost among during the night; and this they more frequently do as the trees lose their foliage, and winter advances. The males on these occasions make a noise which is technically called "cocketing," which they repeat three or four times; but the hens utter one shrill whistle only on flying up, and then remain silent. The sportsman reckons the pheasant a bird of easy conquest, owing to its size and awkward noisy flight; and it is even reputed stupid, because, when roused, it will often perch on a neighbouring tree, and have its attention so rivetted on the dogs as to suffer the sportsman to approach very near. The old cocks, however, have been observed to have recourse to various stratagems, in thick and extensive coverts, before they are compelled to take wing; and Le Roy has remarked, that they regulate the hours of their repast by the seasons. The crowing of the males, which commences in the beginning of March, may be heard very frequently at a considerable distance.

There are many species or varieties of pheasants (for in these birds it is not a very easy matter to distinguish what is a species and what a variety) found in the south-east of Asia, from the islands northward to China. One of the most remarkable of these, in size, in the peculiarity of its plumage, and in the richness produced by various contrasted tints of a few original colours, will be found described in the article ARGUS, and some idea of the appearance of a few of the more elegant ones may be formed upon inspecting the plate "PHEASANTS." The manners of the whole are pretty similar; though, as might be expected, the more recent importations from warm countries are not quite so hardy as those which have long been inured to cold climates. We shall give very brief notices of a few of the more remarkable.

THE GOLDEN PHEASANT (*P. pictus*). The painted pheasants are natives of China, from which they have been introduced into the parks and aviaries of Europe. They are reared in this country with as much ease as the common species, and they appear to be more familiar in their habits. On their first introduction, this was not supposed to be the case, and therefore they were nursed with very great care, and the successful breeding of them was considered even as something very fortunate, notwithstanding all the care which was bestowed on them. That it was fortunate is very true, but the fortune lay exactly the other way

from that which the parties supposed, for they were so much encumbered by the excess of human attention that their native powers were rendered much less efficient than they would have been had they been left altogether alone.

This is a matter worthy of great attention, in the case both of animals and of plants, because there is always more danger that exotics shall, upon their first introduction, be killed by over-kindness than that they shall suffer from neglect. The more beautiful any living or growing thing is, the more are we disposed to associate it with delicacy of frame; and hence we are apt to poison both plants and animals by our heat and confined air, when, if we left them to shift for themselves in a state of nature, they would not only live but become vigorous, and speedily adapt themselves to our climate.—The male bird, when in full plumage, is nearly three feet in length, of which the tail forms two-thirds. The female is not only smaller and has a much shorter tail, but the whole of her plumage is less gay and splendid. The young males resemble the females, and are not invested with all the richness and brilliancy of their attire till they have moulted a second time. The females, on the other hand, at the age of five or six years, sometimes put on the male plumage. From the head rise some long bright yellow feathers, which hang gracefully over its hind part, the colours of which, together with the sides of the neck, are orange and black. The distinctive golden tinge is mixed with green on the back of the neck, the feathers of the back are bright yellow, bordered with crimson; deep blue surmounts the base of the wings, which are beautifully varied with chestnut, brown, and red. The feathers of the tail are chestnut and black; and above the base bright scarlet, which is the colour of all the under parts except the neck, the latter being dusky brown. The iris, bill, and legs are bright yellow. They feed on rice, hemp-seed, wheat, or barley, and they will also eat cabbages, herbs, and fruits; but they are particularly fond of insects, the difficulty of procuring a sufficiency of which is supposed to be a principal cause of the many disorders to which they are liable. The female begins to lay her eggs early in March, which very much resemble those of the Guinea pintado, and are redder than those of the common pheasant. The flesh of the present species is considered superior to that of any of the others. The painted or golden pheasant will breed with the common, but the offspring is infertile in the hybrid, though there is no doubt that, as is the case with all mules, it might be made to breed back to the pure blood of either parent. From their known hardness and their extreme beauty, it were highly desirable that these birds should be multiplied in all ornamental grounds; and it is still more to be desired, though the means of gratifying the desire are not very apparent, that such a feeling should be disseminated among the uneducated ranks of the people, as that they should respect those birds, not only as the property of their lawful owners, which it is a crime against the laws of society to invade, but that they should respect the beauty of such birds as among the public ornaments of their country, the injuring of which is a violation of a much higher law than any which man can enact, and that the consequence of the invasion of this is their own moral degradation, and certain wretchedness and misery.

THE SILVER PHEASANT (*P. nycthemerus*). This

species, which is sometimes called the pencilled pheasant, is still more hardy than the preceding one, and has been reared and domesticated with nearly as little care as the common fowl. Its robust constitution approximates it more to common domestic poultry than the other pheasants. Its education requires only very moderate attention. The form of its caudal plumes, and the mode of their insertion, also present great analogies with the domestic cock. The plumage is less brilliant than that of the golden pheasant, and is about four or five inches shorter. The cheeks are bright red, and the top of the head has long black feathers falling backwards. The back, wings, and upper part of the tail, are of silvery white pencilled with black; the under parts are purplish black. It has two long tail-feathers of pure white; the bill is dusky yellow, and the legs are deep red. The trachea of this pheasant is straight through its entire length, and grows narrow only towards the lower larynx, as in the cocks. The upper part of each bronchus has three demi-rings, which are separated by two wide membranous intervals. The upper larynx and hyoid cartilages are also similar to the same parts in the cocks. The male bird of this species is of a warm constitution. The pairing time is about the latter end of April. The female attends with great assiduity to her young brood, when she has sufficient liberty. The incubation lasts rather more than three weeks. The number of the eggs varies from ten to sixteen; and sometimes, but very rarely, to eighteen. The colour of the eggs is yellowish red, often bordering on black, and they have small brown points on them. It has been brought into almost all the countries of Europe from the north of China, and thrives very well with but little attention.

The plumage of the silver pheasant is by no means so brilliant as that of the golden pheasant; but from the delicacy of the colours and the fineness of the pencilling, and also from the greater lightness of its form, it is doubtful whether it be not the more elegant bird of the two. In length it is usually about four inches shorter than the golden; and its other dimensions are less in the same proportion. The two, however, from the striking differences of their colours make a very agreeable contrast.

THE RING-NECKED PHEASANT (*P. torquatus*). This is likewise a native of China, and closely resembles the common pheasant naturalised in our woods. M. Temminck, however, has pointed out the distinctions with great nicety. There is a white collar about the neck of this bird, from which it takes its name. In 1831 one of the Zoological Society's specimens, which laid eggs the preceding year, exhibited the phenomenon, occasionally observable among birds, of the female assuming the characteristic plumage of the male. The upper parts of this species are blackish, clouded with yellow, and streaked with white; the top of the head is yellow, clouded with green; over the eyes are two white markings; the sides of the hind head, the upper part of the neck and the throat are green, with brilliant purple reflections; and, as already hinted at, there is a large white collar on the neck, which extends towards the sides. The breast is reddish purple, clouded with violet; the middle of the under part whitish yellow, spotted with violet; and the abdomen black, with metallic reflections. The wing-coverts are grey, clouded with green; and the quills olive, waved with large bands of black. The tail-coverts are bright green, the feet grey, and

the bill and irides yellow. The length of the male is about nine and twenty inches. The female is much duller in the plumage, and is marked over the eyes by a streak of short black feathers.

**REEVES'S PHEASANT** (*P. Reevesii*). This is likewise from China, and was unknown in England, at least in the living state, until the establishment of gardens for the reception of animals by the Zoological Society of London. A specimen, sent to the garden by Mr. John Reeves of Canton, arrived in safety, but another one died by the way. The bird is from the north of China. It is a splendid species, the middle feathers of the tail in the male bird measuring between five and six feet in length. It is *Phasianus veneratus* of Temminck.

There are numerous other pheasants, most of them finely coloured, of which specimens have been brought from China, especially from the northern parts of that country. The north of China seems indeed to be remarkably well adapted as a pasture for pheasants; for the species or varieties which have been obtained from thence are larger and finer in their plumage than those of the south of China, or even farther to the south. And it is highly probable that in this grand head-quarter of the genus, there still exist many species which are unknown to Europeans.

The north of China has a very severe winter, as cold as it is in the middle latitudes of Sweden, which is considerably more rigorous than it is in the extreme north of the British islands, while the heat in summer is as great as in northern Africa, near the borders of the desert. So great a range of temperature in the course of the year must be very trying to the constitutions of the wild animals; and those which can bear such alternations of heat and cold must be regarded as especially hardy. This is an important consideration in the natural history of the finer species of pheasants, because it furnishes the most conclusive proofs that those most elegant and highly ornamental birds could be introduced without difficulty into any part of the British islands, at least without the least chance of injury from the winter. This is a consideration well worthy the attention of those who wish to combine beauty with usefulness in the stocking of their parks; but it is one upon which our limits prevent us from enlarging further, and so we must pass on to another genus of the family.

**PAVO**—the peacock. This is a genus which has been long known and generally admired, and it is, in some respects, one of the most beautiful of birds. The generic characters are: the bill naked at the base, convex in the upper part, thickened, and bent downwards at the tip; the nostrils open; the cheeks partially bare of feathers; the feathers of the rump elongated, broad, capable of being spread out like a large fan, and marked with ocellated spots of beautiful form and most brilliant colours; the true tail is wedge-shaped, and consists of eighteen feathers, the extending of which assists greatly in producing the regular fan formed by the feathers of the rump; the head is furnished with a crest; the feet have four toes each; and the tarsi are furnished with conical spots.

**COMMON PEACOCK** (*P. cristatus*). The crest on the head is compressed laterally. The body of the male is golden green, glossed with bronze reflections; and the wing-coverts green gold, glossed with bronze and blue, the colours in all these parts being remarkable for the beauty of their iridescent play of different colours. The under parts of the body are dusky, but

clouded and relieved with green gold. On each side of the head there are two stripes of white. The upper tail-coverts, or rump-feathers formerly alluded to, are very long, and adorned with various colours and beautiful eyes and arches. Indeed there is not a flower in the garden, a metal, a gem, or a tint in the rainbow, which does not find its rival in one part or other of the peacock. The details of the markings could not be enumerated, except in a very lengthened description; and this description, however it might be laboured, would convey but a very faint idea of the splendour of the original. Some of the pheasants, which we noticed in enumerating the leading species of the last genus, are tame in words compared with what they are to the eye; and therefore it would be vain to hope, by means of words, to convey any idea of the peacock. Perhaps the most expressive compliment which has been paid to this bird is a mythological one; the ancient fabulists having deemed the peacock the only animal fit for being yoked to the car of the queen of heaven. But splendid as this bird is, much description is not necessary; for it is so common and so hardy, that, in almost any part of the British islands, only a very short journey is necessary to get a sight of it.

The ordinary length of the full-grown peacock, from the tip of the bill to the extremity of the tail, when in the finest condition, is about four feet. The female is considerably less; and her train is not only very short, but destitute of those resplendent beauties which ornament the male; her crest too is much shorter, and her whole plumage partakes of a sober cinereous hue; her throat and neck are green, and the spots on the side of the head are larger than those of the male. The females of this species, however, like those of the pheasant and of some other birds, have occasionally been known to assume the male attire.

As is the case with most birds in a state of domestication, peacocks often exhibit considerable variety in their colours. Some, for instance, have the wings crossed with small stræ; others have the wings, cheeks, throat, and anterior parts of the belly, and also the wing-coverts white; and specimens in a state of perfect albinism have occurred, in which scarcely one departure from white could be discerned in the whole bird, except that the white on the eye-spots of the tail seemed a little duller than in the other parts of the same feathers.

From the number of peacocks which are still found in India, especially in the richly wooded dells of the western ghats, not a doubt can be entertained of India being the native country of these splendid birds. Some of the places which they inhabit there are peculiar and picturesque in a very high degree. There are often circular valleys, or as one might almost call them cauldrons, so narrow that the eye of one standing on the brink can overlook their whole extent, so deep and so steep in the sides that it is impossible to descend into them, and with the outlet so rough and so choked with vegetation that a passage that way is equally difficult. In those singular places, peacocks may be often seen in swarms; and the brilliancy of their colours adds greatly to the other characters of those curious places. Of course they feed on the ground, in the openings between the trees; but the places of their repose, both when resting for the day and for sleeping in the night, are upon the topmost branches, where they make a very brilliant appearance.

In this country the peacock is a very hardy bird, braving, out of doors, all changes of the weather, and roosting in the lofty trees, instead of seeking the same humble shelter as the common fowls. It is worthy of remark, as a peculiarity in the natural history of those splendid natives of tropical climates, that they are found wild in the forests of the north of Europe. Of course they are not indigenous there, but have escaped from confinement, finding the forest more congenial to their habits than the vicinity of human abodes. It is in Norway that they are understood to spend the summer months; but in the severity of the Scandinavian winter they are frozen out, and are obliged to take their departure for more genial climates. It should seem, however, that the cause of this is want of a due supply of food, rather than incapacity to bear the severity of the winter. At that season of the year they are said to migrate into Germany, where, though the winter is still cold, they seem to meet with a more abundant supply of food. This fact, which appears to be well authenticated, is deserving of attention by those who are interested in promoting the natural decorations of the British islands; for if wild peacocks can live in Norway, and have voluntarily taken up their summer abode there, there is little doubt that they could, if the numbers were carefully increased, summer and winter in almost any part of our islands; and if we had our forests stocked with peacocks, it would add greatly to their beauty and interest.

When in a state of nature, and in the native localities of the south, the peahen is described as breeding only once in the year; but the accounts state that the eggs are very numerous, consisting of as many as twenty-five, or even thirty, at a hatch. These eggs are of a whitish colour, with dusky speckles; and the female is understood to deposit them in some concealed spot, where they may be secure not only from beasts of prey and snakes, but also from the male, who is very apt to destroy them. In our northerly climate, and in a state of domestication, the peahen is not nearly so prolific. The number of her eggs seldom exceeds five or six, and her time of incubation varies from twenty-five to thirty days, according to the temperature of the place and the season of the year. In the warm parts of Europe she is more prolific. For instance, in Greece, she lays from ten to twelve eggs; and, in the absence of her male, she will likewise produce barren eggs, which the ancients termed "zephyrian," as they were supposed to result from the genial stimulus of the vernal gales. When pleased or delighted, and in sight of his females, the cock erects his tail, unfolds his feathers, and frequently turns slowly round, as if to catch the sun-beams in every direction, accompanying this movement with a hollow murmuring. His cry at other times is very unpleasant, which is frequently repeated, especially before rain. He sheds his superb plumes every year, and then, as if conscious of his loss, he courts the most obscure retreats, till the returning spring renews his lustre. The young acquire the perfect brilliancy of their plumage in their third year; but in cold climates, they require attention in rearing, and should be fed on grass, meal, cheese, crumbs of bread, and insects, until they are seven or eight months old, when they will eat wheat, and various kinds of grain, like other gallinaceous birds. In this respect, however, the peacock is extremely capricious, and there is scarcely any kind

of food which it will not, at some time or other, pursue. Tender plants and insects are often eagerly sought for at a time that it has a sufficiency of its natural food at command; and during the indulgence of these unnatural appetites, walls cannot easily confine it; it strips the tops of houses of their tiles or thatch, lays waste the labours of the gardener, roots up his choicest seeds, and nips his favourite flowers in the bud. In India one of its most mischievous propensities is picking at the eyes of children, which it probably takes for some glistening object of prey. It lives about twenty-five years, according to Aristotle, but Willoughby and others allege that it is capable of existing for near a century. When full grown it is not readily injured by cold, and an instance is quoted of one which was found quite frozen, and had lain for some days in the snow, in the court yard of a house in Dunkirk, in the year 1776, and which, by the application of a gentle heat, recovered from the accident, and continued to live as if nothing particular had happened. These birds are also found to thrive in North America, notwithstanding the severity and duration of the winter season. In our cold climates, however, they seem to be incapable of very extensive flights; but they roost aloft in trees, or on the tops of houses or steeples, whence they utter their discordant scream. Though long naturalised in Europe, they are of eastern origin, occurring in the greatest profusion in the neighbourhood of the Ganges, and in the extensive plains of India, particularly in Guzerat, Cambay, the coast of Malabar, the kingdom of Siam, and the island of Java. As early as the days of Solomon they were imported into Judea by the fleets which that monarch equipped on the Red Sea, and which, in all probability, traded to the coast of Malabar. From India they were brought into Asia Minor, and subsequently into the isle of Samos, where they were formerly much multiplied, and consecrated to Juno, but from which they have now wholly disappeared. In the time of Pericles they still fetched a high price in Greece. According to Ælian, thirty years after their first importation into that country, they were exhibited at Athens as a show to strangers; and he adds, that multitudes flocked to see them from Lacedæmonia and Thessaly. Alexander had never seen peacocks till his Indian expedition, when he found them flying about in the wild state on the banks of the Hyarotis, in the Punjab, or land of streams, and he was so delighted with their splendid appearance that he decreed a severe penalty upon any one of his army who should kill or even molest them. He carried them with him on his return, however; and it appears that they had bred freely, for toward the close of Alexander's short but brilliant reign, Aristotle speaks of them as birds familiarly known in Greece. The account of their importation into the country of the Jews, at a more early period than this, which is stated in the English translation of the Bible, is in all probability a mistake of the translators; because, if the living birds had been introduced there, it is highly probable that they would have found their way into other parts of the western world. They were not introduced into Rome till about the time of the decline of the republic; and, according to the account given by Pliny, the orator Hortensius was the first who introduced them at table, in a feast which he gave to the company or college of augurs. His example was, however, soon followed by others; and, as the luxury of the Romans consisted fully as much

in the mere ostentation of expense as in the real gratification even of the palate, they were even in great demand for the more splendid feasts, and rose to a most exorbitant price. When the Roman emperors had lost even the savage virtues of the earlier ages, in more ostentatious dissipation, they took a pride in having at their tables large dishes wholly composed of the heads and brains of peacocks, for the introduction of which there could be no imaginable motive but the great expense. With the epicures of modern times, the peacock is in small favour; and though the young are eaten, but not much in request, the full grown birds are not. Their flesh is tough, and has not a very agreeable flavour. The hardness of the flesh has, however, one advantage (if advantage it can be called) in hot climates, it resists putrefaction longer than the flesh of almost any other animal.

In the American continent, or even in Africa, there is no trace whatever of these birds as natives, but they have been introduced into both. The Portuguese, when they had the ascendant both in India and in Africa, introduced them into the latter country, where they were highly prized by the native princes. At later periods of history they have been introduced into various parts of America and the West Indian islands. In all countries they are regarded more in the light of mere ornaments than of any thing else.

Though these birds are hardy in enduring the weather, they are very sensitive to its changes, and give note of some of those before there are any indications which are palpable to the majority of the human race. In summer the screaming of peacocks, especially towards the close of the day, is understood to prognosticate rain, and they are not the only birds which naturally perform this sort of augury.

THE THIBET PEACOCK (*P. Thibetanus* of Linnæus) ought perhaps to be referred to another genus, and Temminck has done so, designating it by the generic name of *Polyplectron*, and specifically as *Polyplectron chinquis*. Cuvier, however, retains it in the genus *Pavo*, to which it is certainly allied. Its colour on the upper part is a bluish black, with metallic lustre; the feathers being bordered with golden green, beyond which there is a fringed margin of deep black. The top of the head is covered with short feathers of a soft velvety texture, of a golden green colour with blue reflections; and these feathers are surmounted by a tuft of twenty long and thread-shaped feathers with whitish shafts, and a row of bluish green points along each side, which give the crest the appearance of being toothed. The colour of these lateral points of the crest is very brilliant. The neck, the throat, and the lower part of the breast, are of a greenish blue of a very bright lustre, the feathers having at the end a gold coloured eye-spot bordered with bright blue. The lesser and middle coverts of the wings are green with blue reflections; and the larger coverts are greenish black, bordered with golden green. The quills are yellowish maroon, with the shafts and tips greenish black. The upper tail-coverts are bright golden green marked across with chevron bars of a yellowish colour; the tail-feathers bright green covered with brown. The under parts are black, with golden reflections; and the bill and feet are black. The secondary quills are ornamented with very brilliant blue spots, and the produced upper coverts of the tail with similar spots of green, two upon each feather; but the feathers are not nearly so much produced as those of the common peacock.

These birds are singularly beautiful; they are less than the common peacock, but larger than pheasants. They are found in the mountainous country between India and the Chinese territory; and, according to some of the authorities, they are also found farther south, in the Malay peninsula, and also in the islands. One of their most remarkable peculiarities is the number of spurs on the tarsi of the male, which are sometimes as many as six upon one leg; and there are often more on the one leg than on the other. The feathers of the tail are erectible and may be expanded like a fan, in the same manner as those of the peacock; but though there are more eye-spots on the single feathers, the appearance altogether is not nearly so splendid. The plumage of the female is much less brilliant than that of the male, and the tail-feathers are not nearly so long. The young birds are of an earthen grey colour, with lines and spots of brown. After the first moult, the colours are not so broken and irregular, and the positions of the spots on the wings and tail can be traced. After the second moult, they become more distinct and better defined, and display the rich gold and blue and green, which are so ornamental in the mature birds. It is not, however, till after the third moult that the colours attain their highest perfection. Even in the state of nature this species is by no means wild; and when in confinement, it is very soon reconciled to its condition, and breeds as freely as any other of the race. Altogether it is a very beautiful and highly interesting bird. The quality of its flesh as an article of domestic economy has not been mentioned, but the probability is that, from the similarity of the general appearance, it may in the adult state partake of the harshness of that of the common peacock.

Varieties of the peacock have been mentioned as occurring in the East of larger size and more brilliant plumage than the common variety found in Europe; but the probability is that they are only accidental, or at most caused by a more congenial climate; for it has been noticed that peacocks in the north of Scotland are inferior in point of beauty to those of the warmer parts of England; and it is known that those which are met with in Norway and Sweden are smaller in size, and less beautiful in plumage than in the south of Europe.

THE JAPAN PEACOCK (*P. muticus* of Linnæus) appears, however, to have some distinct characters. We might indeed expect this from the simple fact of its being a native of the Japan isles; for it should seem that there is nothing native in those singular islands, whether animal or vegetable, exactly like the productions of any other country, how much soever it may agree with them in its common generic characters. The Japan peacock is very nearly of the same size and general character with the common or Indian one; and like that, it has the tarsi armed with a spur on each. The crest, however, is of a different character, being composed of ten graduated feathers, which are reflected backwards. The cry is also different from that of the common species. We are not aware that any living specimen of it has been, at least of late years, brought to Europe.

LOPHOPHORUS. This genus, which has no very accurate English name, is an inhabitant of the mountainous parts of the north of India. The characters are: the head surmounted by a crest, consisting of detached silky feathers of unequal length, and reflected backwards; the tail is rounded, and the coverts are

not produced, as in the peacocks; the colours of the male have a very brilliant metallic lustre; and the tarsi are furnished with spurs.

*Lophophorus refulgens* is about the size of a turkey. The general colour is black; but the crest and feathers of the back are relieved by very brilliant reflections of gold and bronze colour, and also bright blue and bright green; the tail-feathers are red. The prevailing colour of the female and the young birds is brown, clouded with grey and yellowish. The most remarkable character of these birds, and one in which they differ from all the rest of the order, is that of the bill, which is altogether a long one, and the upper mandible projects a considerable way over the under one, and is truncated at the tip. This mandible is much arched, very strong, and advances on the front of the head between the feathers. It has a strong rounded ridge all along the culmen, with a groove on each side. The under side of it is very much hollowed, and the upper mandible shuts so completely into it as to be invisible when the bill is closed. What particular purpose this singularly-formed bill answers in the economy of the bird has not been ascertained, but it must refer to some peculiarity in the food or the manner of feeding. The legs are rather short but very strong, and the feathers on the tibiae are so much produced as to hang down nearly as far as the spurs on the tarsi.

*Lophophorus Cuvierii* has the same characters of bill as the other species or variety; but the crest is pendent backwards, and the feathers on the upper part are margined with white. It is also smaller in size than the other, though larger than any of the pheasants. The feathers on the tibiae are also less produced. The female is less than the male, of a brown colour, and with white edges to the feathers on the breast.

Both these species belong to nearly the same locality, and both are mountain birds, found chiefly, if not exclusively, in the mountainous countries between India and China, not, we believe, on the more lofty ridges and summits of the Himalaya, but on the secondary hills and in the upland valleys. In the south of India, and even in Bengal, they are unknown as native birds; for even at Calcutta they are brought from the north, and esteemed as curiosities.

*Lophophorus Cuvierii.*

It does not appear indeed that there is, on the mountains within and near the tropics, any gallinaceous birds agreeing in character with the ptarmigan and other species of mountain grouse of the north. In air and appearance the present birds corresponds in part with the peacocks, in part with the common fowl, and in part with the pheasants; but they differ

so much from any one of these, that they are properly made a distinct species.

**TRAGOPON.** This genus was by the elder naturalists included among the pheasants, under the title of the "horned pheasant," from two appendages of the head to be afterwards noticed; and it was also called the Nepal pheasant, from the country in which it was first discovered. In all its characters, and in its general air and appearance, it is, however, very different from the pheasants; and in the shape of the body, and the carriage of the head and neck, it much more nearly resembles a common fowl. The forehead and cheeks are almost naked; the hind part of the head has a crest of loose detached feathers inclining backwards; there is a slender horn sticking out behind each eye; and the wattles under the throat are capable of being extended. The upper parts of the male bird are bright red, spotted with white, the white being surrounded with a ring of black; and on the coverts of the wings and upper part of the tail those spots are larger and more distinctly eye-shaped than on any other part of the body. The neck and breast are orange, with white spots surrounded with black; and those spots become larger on the flanks and thighs.

Nepal Horned Tragopon (Pheasant).
